

# AN INFRARED STUDY OF THE MAGELLANIC CLOUDS

Piet Schwering

*Promotiecommissie:*

<i>Promotor:</i>	Prof. Dr. H.J. Habing
<i>Co-promotor:</i>	Dr. F.P. Israel
<i>Referent:</i>	Dr. J. Koornneef
<i>Overige leden:</i>	Prof. Dr. W.B. Burton Prof. Dr. A. Blaauw Prof. Dr. H. van de Laan Prof. Dr. G.K. Miley Prof. Ir. C. van Schooneveld Prof. Dr. W.J. Huiskamp

The Infrared Astronomical Satellite (IRAS) was developed and operated by the Netherlands Agency for Aerospace Programs (NIVR), the U.S. National Aeronautics and Space Administration (NASA) and the U.K. Science and Engineering Research Council (SERC).

### Gracias a la Vida

*Gracias a la vida que me ha dado tanto,  
me dió dos luceros que cuando los abro  
perfecto distingo lo negro del blanco,  
en el alto cielo su fondo estrellado,  
en las multitudes la mujer que yo amo.*

*Gracias a la vida que me ha dado tanto,  
me dió el corazón que agita su marco  
cuando miro el fruto del cerebro humano,  
cuando miro el bueno tan lejos del malo,  
cuando miro el fondo de tus ojos claros.*

Violeta Parra

### Mijn dank aan het leven

*Mijn dank aan het leven dat me zo véél heeft gegeven,  
het heeft me twee ogen gegeven zodat ik, wanneer ik ze open  
perfekt het donkere van het lichte kan onderscheiden,  
in de hoge hemel de besterde verte,  
in de menigten de vrouw die ik liefheb.*

*Mijn dank aan het leven dat me zo véél heeft gegeven,  
het heeft me mijn hart gegeven dat zo heftig klopt  
als ik de vrucht bekijk van het menselijk brein,  
als ik de goede mensen zo ver verwijderd zie van de slechte mensen,  
als ik de diepte zie van jouw heldere ogen.*

*The Antarctic Pole is not so starry as the Arctic. Many small stars clustered together are seen, which have the appearance of two clouds of mist. There is but little distance between them, and they are somewhat dim. In the midst of them are two large and not very luminous stars, which move only slightly. Those two stars are the Antarctic Pole.*

*Pigafetta (1520)*

## Chapter I

### INTRODUCTION

#### 1. The earliest observations of the Magellanic Clouds

Before the invention of the telescope only three galaxies had been seen with the naked eye, only one of which appeared in a catalogue. The Persian astronomer Al-Sûfi (903 – 986) recorded the Andromeda nebula for the first time in his star catalogue "Book of Fixed Stars" (964). The other two galaxies are the Magellanic Clouds, first described by Magellan's chronicler Pigafetta, after leaving the Estrecho de Magallanes in 1520. These two closer and therefore brighter galaxies were discovered later, since they are located in the southern hemisphere beyond the reach of traditional astronomers in Europe and Asia. However, according to Wilson (1899), Al-Sûfi possibly knew the Large Cloud, which he might have meant with an object called Al-Bakr ("white ox").

The Magellanic Clouds were known since the first voyages to the southern hemisphere. They were discovered by Portuguese seamen in the 15<sup>th</sup> century and named in honour of Fernão de Magalhães e Sousa, who undertook the first voyage around the world. They are mentioned from 1516 on, when the Italian navigator Andraes Corsali drew a map of the southern sky. The two objects, which look like clouds (Pigafetta *et al.*, 1962), were important to 16<sup>th</sup> century sailors for navigation purposes. Strangely enough the Magellanic Clouds do not appear in Messier's Catalogue of nebulae (1784), which indeed was biased to the northern hemisphere. Herschel claimed to have observed a connection between the Large Cloud and the Milky Way Galaxy on clear nights in 1838; i.e. an indication for interactions between these two galaxies. The New General Catalogue of Nebulae and Clusters of Stars and the Index Catalog (Dreyer, 1888, 1895, 1908) contain various objects in both Magellanic Clouds.

## 2. Modern observations

### 2.1. The Local Group of galaxies

In 1912, Leavitt discovered that the period and luminosity of pulsating Cepheid variable stars in the Small Magellanic Cloud were related, giving a key to measurements of stellar distances. Shapley calibrated the relation in 1917. Some years later Cepheids were found in the Andromeda nebula (from now on M31), revealing that spiral nebulae were indeed other galaxies at immense distances. In 1925 it became clear through the work of Hubble, that most of the nebulae are "island universes" outside our own Milky Way Galaxy. The Galaxy is a member of a small group of galaxies called the "Local Group". Thirty (mostly small) members are now known within the Local Group. The two dominant galaxies are M31 and our Galaxy. They are surrounded by a number of smaller galaxies; the Magellanic Clouds are satellites of our Galaxy.

Tidal interactions between the Clouds and the Galaxy have played an important role in the evolution of the Clouds, and in forming the present structure. These interactions are indicated by distortions of the Small Cloud (Mathewson and Ford, 1984), the existence of the Magellanic Stream (a narrow band of neutral hydrogen) and the HI bridge between the Clouds. Lynden-Bell (1962) has suggested that many of the dwarf galaxies surrounding our Galaxy are tidal debris of an encounter between the Large Cloud and our Galaxy. At the moment, the Small Cloud seems to be breaking up into a Small Cloud-remnant and a Mini-Magellanic Cloud (Mathewson and Ford, 1984).

### 2.2. The Magellanic Clouds

Because of their position the Clouds can only be observed with southern hemisphere telescopes. Yet astronomers at all continents are studying the Galaxy's closest neighbours. The Large Magellanic Cloud (LMC) is located in the constellation Dorado and has an optical diameter of about  $7^\circ$  (Fig. 1). The Small Magellanic Cloud (SMC), with a diameter of  $3.5^\circ$ , is located in Tucana (Fig. 2). On deep plates they have diameters of  $12^\circ$  resp.  $8^\circ$ . The Magellanic Clouds are presumably gravitationally bound,  $22^\circ$  (25 kpc) apart. They are the nearest galaxies, more than ten times closer than M31, the closest spiral galaxy, and can be resolved into individual objects and nebulae. They are close enough that we can perform detailed investigations and henceforth use them as a link between the Milky Way and more distant galaxies.

The Clouds are regarded as blue irregular galaxies and have low luminosities (classes III – V). The LMC-Bar resembles the central bar of a barred spiral. Some evidence for the beginning of a spiral pattern at the ends of the Bar was found by de Vaucouleurs (1955); it was shown later that these arms are Galactic foreground material (Israel and Schwing, 1986). According to some authors (e.g. Schmidt-Kaler, 1977), the LMC's active filaments show spiral structure emerging from the 30 Doradus nebula. A thorough description of the morphological structure of Magellanic type galaxies is given by Feitzinger (1980).

Hodge and Wright (1967) presented an optical atlas of the LMC. The LMC is a true astronomical treasure-house. It contains objects as the Tarantula nebula (NGC 2070; better known as 30 Doradus), one of the largest known HII regions; the most luminous individual star known in the universe S-Doradus (the chief star of the cluster NGC 1910). Shapley has named ten major Constellations of active star formation in the LMC (van den

**Figure 1.** *The Large Magellanic Cloud.*

A black and white negative-print of a visual exposure obtained with the 61-cm Schmidt telescope of the Cerro Tololo Inter-American Observatory (CTIO). The figure shows the central region of about  $6^\circ \times 4^\circ$ . Clearly visible are the LMC-Bar, and the 30 Doradus complex at the left. The bright region at the top of the image is Constellation I, and the region between 30 Doradus and the Bar is Constellation II. Many Galactic foreground stars are visible.

**Figure 2.** *The Small Magellanic Cloud.*

A negative-print of an ESO-SERC Sky plate. The total field is  $6^\circ \times 6^\circ$ . Many Galactic foreground stars are visible, as well as the Galactic globular cluster 47 Tuc at the right.

Bergh, 1981). Supernova SN 1987A in the LMC, became one of the most studied objects of 1987 (various ESO astronomers and ESO guest observers; see *Eso Messenger* 47, 1987, pp 26 – 35).

Hodge and Wright (1977) presented an optical atlas of the SMC. The SMC, overshadowed by the larger LMC, contains few regions of bright nebulosity and the stellar population is less flamboyant. There are two main areas in the SMC; a Bar, and a Wing that was described by Shapley in 1940. The SMC HII region N 66, is referred to as a small copy of 30 Doradus in the LMC (Lequeux, 1987).

Without aiming for completeness, here follows a summary of the main Cloud surveys. Feast *et al.* (1960) listed the brightest stars in the Clouds, and found 50 stars in the SMC and 108 in the LMC. Azzopardi and Vigneau (1982) have enlarged the list of SMC stars to 524. The list of LMC stars was expanded by Sanduleak (1970) to 1272 with  $m_{pg} < 14$ . Fehrenbach and Duflo (1970, 1973 and 1981) observed 2990 stars in and towards the LMC. Various surveys were published for special types of stars and stellar products.

A total of 122 stellar associations are listed by Lucke and Hodge (1970) for the LMC and 70 by Hodge (1985) for the SMC. Up to now 601 star clusters have been identified in the SMC (Kron, 1956; Lindsay, 1958; Westerlund and Glaspey, 1971; Hodge and Wright, 1974; Brück, 1976; Hodge, 1986). A number of 1603 clusters were identified in the LMC (Shapley and Lindsay, 1963; Lyngå and Westerlund, 1963; Hodge and Sexton, 1966). Both globular and open clusters with various degrees of concentration have been found. The ages of these clusters range from  $10^7$  yr to  $10^{10}$  yr and on average these clusters are more flattened than their Galactic or M31 counterparts (van den Bergh, 1984). The Clouds are surrounded by a number of young globular clusters.

### 2.3. Atomic, molecular and ionized gas

The first atomic hydrogen (HI) surveys of the Clouds were published by McGee and Milton (1966) on the LMC and Hindman (1967) on the SMC. Later surveys are by Rohlfs *et al.* (1984) and McGee and Newton (1981). All of them were obtained with the 64-m Parkes radio telescope (CSIRO) which has a resolution of  $15'$  at 1420 MHz. Although the LMC is larger than the SMC the HI masses are about the same for the two systems. Both galaxies contain a large fraction (10 % for the LMC and 30 % for the SMC) of the total dynamic mass in the form of HI. Neutral hydrogen observations also reveal the existence of a great gaseous envelope surrounding both Clouds (Mathewson and Ford, 1984).

An overview of radiocontinuum surveys of the Clouds can be found in Mills and Turtle (1984). Most of the high resolution surveys were obtained with the 64-m Parkes telescope; the latest being the 1400 MHz survey by Haynes *et al.* (1986). The Molonglo Observatory Synthesis Telescope (MOST) has yielded a high resolution ( $< 1'$ ) map of the Clouds at 843 MHz (see Mills and Turtle, 1984). The radio observations show both thermal and non-thermal radio emission. The first component is related to individual HII regions, while the latter is related to the galactic disk.

The first detections of molecular carbon monoxide emission in the Clouds were by Huggins *et al.* (1975; CO 2.6-mm), Israel *et al.* (1982; CO 1.3-mm), and Israel *et al.* (1986). The first complete CO surveys of the Clouds was presented by Rubio *et al.* (1984) and Cohen *et al.* (1984), obtained with the Columbia Southern Millimeter-Wave telescope at CTIO, with a resolution of  $8'$ . Final LMC CO maps are presented by Cohen *et al.* (1988).

A low CO abundance is indicated by all of these observations, which may imply molecular hydrogen underabundances. Presently, a large CO survey of the Clouds with the ESO-SEST telescope is underway; this survey has just started and will take years to complete (Israel, priv. comm.). In these galaxies the abundance of CO with respect to  $H_2$  may be different from that in the Milky Way (Israel, 1985). The first molecular hydrogen observations of objects in the Clouds were obtained by Koornneef and Israel (1985) for N 81 in the SMC. Israel and Koornneef (1987) have observed the S1-line and Q-branch of  $H_2$  in some 10 objects of both Clouds. A summary of observations of other molecules than CO and  $H_2$  of the Clouds can be found in Israel (1984).

Henize (1956) published  $H\alpha$  photographs and a list of 221 nebulosities in the LMC and 90 in the SMC. Davies *et al.* (1976) obtained new photographs and listed 329  $H\alpha$  nebulosities in the LMC and 167 in the SMC. Kennicutt and Hodge (1986) added  $H\alpha$ -fluxes for most of the HII-regions. From the  $H\alpha$  photographs Meaburn (1980) found numerous giant shells and 9 supergiant shells (with sizes of  $\sim 1$  kpc) in the LMC and 1 supergiant shell in the SMC.

#### 2.4. Abundances and star formation

The Magellanic Clouds show low heavy element abundances. A summary of these abundances is given by Dufour (1984). In Cloud HII regions, O and Ne are deficient (relative to HII regions in the Solar Neighbourhood) by a factor of 2 in the LMC and 5 in the SMC. The deficiency of C and N is even larger, 4 and 16 times in the LMC and 30 times in the SMC. Hence, the metallicities in the SMC are more extremely underabundant than in the LMC.

With the use of balloons and spacecraft, ultraviolet studies have become available (Carruthers and Page, 1977; Koornneef, 1977; Vuillemin, 1988). These studies show strong radiation fields produced by hot OB-stars. The global star formation rate in the Magellanic Clouds (Lequeux, 1984) is higher per unit total mass in the Clouds than in the Galaxy (2.7 times in the LMC and 1.6 times in the SMC). Several bursts of star formation seem to have occurred in the LMC. Kennicutt and Hodge (1986) have estimated the total star formation in the Clouds at  $0.14 M_\odot/\text{yr}$  in the LMC and  $0.038 M_\odot/\text{yr}$  in the SMC. A number of protostars has been detected in both Clouds by Gatley *et al.* (1981), Gatley *et al.* (1982) and Jones *et al.* (1986).

Optical photometry shows that the Magellanic Clouds suffer little obscuration by dust. The dust content of the Clouds has been studied in different ways. A summary of dust observations is given by Israel (1984). Hodge (1972) listed 68 dark clouds in the LMC and Hodge (1974) listed 45 dark clouds in the SMC. These lists are not complete due to the fact that dark clouds are only seen on a stellar background. Dust is underabundant in the Clouds, resulting in gas-to-dust ratios 4 (LMC) and 17 times (SMC) higher than in the Galaxy (Koornneef, 1984).

Interstellar extinction curves of the Clouds are presented by Koornneef and Code (1981) for the LMC and by Lequeux *et al.* (1984) for the SMC. The general characteristics are that the 2200 Å bump is weaker in the LMC than in the Milky Way, and it is completely absent in the SMC. The far-ultraviolet rise is steeper in the LMC than in the Milky Way; and even steeper in the SMC.

### 3. Outline of this thesis

One of the principal motivations for studying the Magellanic Clouds is the high linear resolution that can be achieved. At distances of 53 kpc (LMC) and 63 kpc (SMC; Humphreys, 1984), details of order 10 times smaller than in the nearest spiral galaxy M31 and 50 times smaller than in comparable (dwarf) irregular galaxies can be seen.

In Fig. 3 the integrated flux densities of the Clouds over the whole spectral range are shown. The newest observations are the infrared data, obtained with the Infrared Astronomical Satellite (IRAS), which have the highest flux densities. These IRAS observations indicate the importance of filling in the infrared gap in the spectrum. This thesis deals with the infrared spectral range. Due to the fact that the atmosphere absorbs most energy at wavelengths between 20 and 1000  $\mu\text{m}$  (Traub und Stier, 1976), far-infrared observations can only be obtained by balloon-borne telescopes or satellites.

**Figure 3.** Integrated flux densities  $f_\nu$  of the Magellanic Clouds.

The dashed curves are eye-bal fits to the data points. Note the offset between the left-hand (LMC) scale and right-hand (SMC) scale. The solid line represents the zero-level for the energy spectrum ( $\nu f_\nu$ ).

The next two chapters deal with the IRAS infrared observations that form the basis of this study. In Chapter II, the SMC observations are presented in the form of maps at 12, 25, 60 and 100  $\mu\text{m}$ . From these maps a list of 219 discrete infrared sources is extracted. This source list is compared to known object lists (foreground stars, SMC stars,  $\text{H}\alpha$  nebulosities, clusters, supernova remnants, planetary nebula and dark clouds). In an Appendix to this chapter, a discussion of two fields at the SE and SW edge of the SMC are discussed. These areas contain 29 sources, which are also compared to other source lists.

Chapter III deals with IRAS infrared observations of the LMC. A similar presentation and discussion is given as for the SMC. A list of 1823 discrete sources is extracted, which are compared to other source lists. Seven fields at the North and West edges of the LMC are discussed in an Appendix to this chapter. These fields contain another 68 sources, which are also compared to other source lists.

In Chapter IV a discussion of the Galactic infrared foreground is presented. Especially towards the LMC, foreground filaments disturb the image of the Cloud. Observations are normally corrected for a constant Galactic foreground of  $E_{B-V} = 0.07$  mag. The IRAS data suggest strong variations in the foreground (Israel and Schwope, 1986). The relation between the infrared foreground emission and the atomic hydrogen content is discussed; it is found to be non-linear. Temperature corrected infrared maps are produced, which are compared to the atomic hydrogen emission. An estimate for the foreground infrared emission is derived, based on the average observed gas-to-dust ratio. A more or less constant foreground of 0.08 mag towards the SMC is found. The foreground towards the LMC varies from 0.07 to 0.17 mag, with an average of 0.10 mag and minima in the directions of 30 Doradus and the Bar.

Chapter V deals with the large scale and global properties of the Magellanic Clouds. Integrated infrared flux densities are derived, infrared sizes, luminosities and temperatures. The infrared morphology is discussed, together with the temperature distribution. From the latter, the interstellar radiation field in the Clouds is estimated. At the outer edges of the Clouds we found radiation fields equal to the Solar Neighbourhood field and in HII regions the field is 10 – 20 times stronger. Comparisons of the infrared maps are presented with ultraviolet data,  $\text{H}\alpha$  maps and with radio continuum observations.

In Chapter VI a discussion is given of the dust properties in the Clouds. The mid-infrared (12 and 25  $\mu\text{m}$ ) emission is discussed in detail. Most probably very small grains are responsible for this emission. Dust masses are derived for the combined warm ( $\sim 50$  K) and cool (25 K) dust components. The mass present in a cold (15 K) dust component is estimated to be 30 – 100 % of the mass of cool dust. The mass of hot ( $\sim 300$  K) dust is  $10^{-5}$  times that of cool dust. Dust column density maps are presented for both Clouds. From a comparison of the infrared maps with HI maps, similar non-linear relations are found as for the Galactic foreground in Chapter IV.

Chapter VII contains a further discussion of the global properties of the Clouds. It also contains a discussion of the global relation of the Clouds to (dwarf) irregular galaxies and the relation to Local Group galaxies. Relations between the Clouds global properties derived from the global infrared data, and data at 8' resolution, are established. An extensive discussion on the gas-to-dust ratios in the Magellanic Clouds is presented. This ratio is 3 times higher in the LMC compared to the Galaxy and 55 times in the SMC.

Finally, a summary of the quantities involved in IRAS observations is given in an Appendix. A review of the far-infrared radiative transfer theory is given. The Appendix contains tables and figures for colour corrections, dust temperature and mass calculations and bolometric corrections.

A summary of this thesis in English, Spanish and Dutch is given at the end. An atlas of the detailed IRAS infrared images of both Magellanic Clouds is presented by Schwering and Israel (1988).

## Chapter II

### INFRARED OBSERVATIONS OF THE SMALL MAGELLANIC CLOUD

#### Summary

Results of IRAS pointed observations in four infrared wavelength bands (12, 25, 60 and 100  $\mu\text{m}$ ) on the Small Magellanic Cloud are presented. Maps with orthogonal scan directions are shown and a source list containing 219 infrared sources is extracted from the data. Comparison with the IRAS Point Source Catalog (PSC) shows that only three entries in this catalogue are spurious. Thirty-three of the sources found (and listed in the PSC) are extended. We confirm all 13 entries in the IRAS Small Scale Structure Catalog (SSS) in the SMC. We found 72 new infrared sources, not included in either the PSC or in the SSS. Our SMC infrared source list is compared to other object lists. We identified 28 SAO stars, two blue globular clusters and seven planetary nebulae. We did not find any SMC-stars nor did we find a clear correlation with supernova remnants. In general there is a good correlation of infrared emission with the distribution of HII regions and dark clouds. Results of infrared maps of two additional fields at the SE and SW corners of the SMC are presented in an Appendix, together with a list of sources that were extracted from these maps.

#### 1. Introduction

The Magellanic Clouds are the closest galaxies in the Local Group. In fact, with distances  $D = 53$  kpc (LMC) and  $D = 63$  kpc (SMC; Humphreys, 1984) they are the nearest (dwarf) irregular galaxies. As a result, with the same instrument linear resolutions on the Magellanic Clouds are of order 50 times better than those on comparable other blue dwarf irregulars, thus enabling terrestrial observers to conduct extensive studies on their detailed structure. Compared to the Solar Neighbourhood, both Magellanic Clouds are characterized by low dust and low heavy-element abundances (see *e.g.* the review by Israel, 1984). Relatively high present-day star formation rates, hence the presence of large numbers of luminous hot stars, nevertheless lead to significant infrared emission from warm dust. Only limited infrared information on the Clouds is available from ground based and airborne observations (see Table 1). All these observations were limited to the brightest a priori known objects and covered negligible fractions of the Cloud surfaces. A complete infrared survey of the Magellanic Clouds was first obtained by the Infrared Astronomical Satellite (IRAS). The IRAS mission (IRAS, 1985a) produced a list of point sources over the whole sky, including the Clouds, as well as a series of maps, both in the Survey mode and in pointing modes, and a catalogue of Small Scale Structure (SSS). However, the IRAS Point Source Catalog (PSC) entries for the Clouds in principle suffer from confusion. Potential effects of this on the PSC are artificial detections and missed real sources. Maps of the sky brightness as observed by IRAS in the 16°5 extended

emission images (Skyflux) and the Additional Observations (AO) program, give better information about (point and extended) sources in the Magellanic Clouds, because they represent two-dimensional images, while the PSC was obtained from one-dimensional detector datastreams. The advantage of the AOs over the 16°5 Skyflux images is the higher resolution, better sampling, better pointing, higher sensitivity and less striping. Because of the position of the Clouds near the Ecliptic Pole many different scan angles occur which fill the present Skyflux maps with radial striping. Due to this striping and other background variations determination of good fluxes for both Magellanic Clouds from the Skyflux maps is very difficult, especially at 12  $\mu\text{m}$ . Here we present full-resolution AO maps of the SMC and information on discrete sources extracted from these maps.

**Table 1.** Other infrared observations of the Magellanic Clouds <sup>a,b</sup>.

Spectral range	Reference	Number of Objects		Objects
		SMC	LMC	
Near-infrared photometry ( $\lambda < 30 \mu\text{m}$ ):				
	Grasdalen and Joyce (1976)	6	0	N9,N13A,N25,N46, N64A,N81
	Price and Walker (1976) <sup>c)</sup>	0	4	30 Dor,N159 (2 more)
	Gatley <i>et al.</i> (1981)	0	1	N159

	Jones <i>et al.</i> (1986)	0	5	N10,N59A,N158C, N160,N159
	Israel <i>et al.</i> (1988)	9	16	Various sources
Near-infrared spectro-photometry ( $\lambda < 5 \mu\text{m}$ ):				
	Koornneef and Israel (1985)	1	0	N81
	Israel and Koornneef (1988)	3	6	N81,N85,N88 (SMC); N7,N83B,N11A,N213A, 30 Dor,N159 (LMC)
Far-infrared photometry( $\lambda > 30 \mu\text{m}$ ) <sup>c)</sup> :				
	Werner <i>et al.</i> (1978)	0	4	30 Dor,N158, N160A,N159
	Jones <i>et al.</i> (1986)	0	4	N159,N160A,N59A,N158

**Notes to Table 1:**

- Near-infrared stellar surveys are excluded: Glass (1974), Allen and Glass (1976), Glass (1979), Feast *et al.* (1980), Catchpole and Feast (1981), Cohen *et al.* (1981), Feast and Whitelock (1984), Glass (1984), Welch and Madore (1984), Russel and Hyland (1985).
- Near-infrared surveys of cluster stars and integrated cluster photometry are excluded: Mould and Aaronson (1980), Aaronson and Mould (1982), Mould and Aaronson (1982), Frogel and Cohen (1982), Persson *et al.* (1983).
- The observations of Price and Walker (1976) were done with a rocket experiment; the far-infrared observations were obtained with NASA's Kuiper Airborne Observatory. The other observations in this table are all ground based.

## 2. Observations and data reduction

The observations presented in this chapter were obtained with the IRAS satellite as part of the AO program carried out with the IRAS survey array. A full description of the instrument array, the survey and data processing can be found in the IRAS Explanatory Supplement (IRAS, 1985a). A description of the AO program and a list of all rasterscan AOs observed by the IRAS satellite of many different objects are given in "A User's Guide to IRAS Pointed Observation Products" (IRAS, 1986).

There is a variety of pointed observations on the SMC (see Israel and Schwering, 1986). Most of them (IRAS AO observation technique DPS) cover an area of  $1.5^\circ \times 0.5^\circ$ , others (DSD) are useful only for small fields on selected objects. Deep Sky Mapping (DPM) observations are the only ones covering the entire SMC in a regular manner. Because these DPM observations are not limited by noise and the resolution cannot be improved by adding the other AO observations, it was decided not to combine observations obtained with different observing techniques. This also avoided possible problems in combining these different AOs, and in having inhomogeneous coverage of the SMC. The maps presented here are thus based on the DPM observations alone. The observations were made in the months of June, July and September 1983, and are summarized in Table 2.

In the DPM mode, a rasterscan of 6 or 7 legs of  $166'$  length was made with a cross-scan step of  $20'$ , while scanning took place in the normal survey direction. Scanning each leg took about 43 seconds with a turnaround time of about 17 seconds, so that observing a single DPM field took about 8 minutes. The scan speed was  $3.85'/\text{sec}$ , as for the survey. Compared to the survey the signal-to-noise ratio increased by a factor of about 1.4.

Deliberately two separate sets of DPM observations were made with almost orthogonal scanning directions: approximately EW and NS. This was possible because the SMC is close to the South Ecliptic Pole ( $\beta_{\text{SMC}} = -65^\circ$ ), so that observations obtained three months apart yielded the required orthogonal scanning directions. Due to the rectangular form of the IRAS survey detectors (largest size in the cross-scan direction) the resolution is highest in the scan direction (timeresolution), so that these two sets of data supply us with maximum resolution in both directions. In June the SMC was scanned NS (average position angle of the scan direction  $159^\circ$ ; observations set 1 NS in Table 2) in a double coverage, in July also NS ( $173^\circ$ ; set 2 NS) with a coverage of four. In September (three months later) the SMC was scanned EW ( $253^\circ$ ; set 3 EW) with double coverage. Because of the large size of the SMC compared to the area covered by a single DPM observation every coverage consists of four differently pointed observations. Another nine observations were made (two in June and seven in July), which were processed and later deleted for various reasons (see below).

The reduction was done in two stages. The first stage of data reduction took place at the IRAS Science Data Analysis System (SDAS). It contained the stim-flash calibration of the detector datastreams (see IRAS, 1985a) to the IRAS May 1984 standard. Dead detectors and the smaller edge-detectors were left out to obtain a consistent sampling for small sources. Detector offsets were eliminated to avoid detector striping in the maps (Kopan, 1984). Because each individual detector had its own gain characteristics and inconsistencies between different detectors in a single band remained, an unacceptably high striping level may result unless special care is taken. The method used reduced the stripes very effectively to a reasonably low level (but non-zero) by positionally aligning

detector datastreams in-scan, histogramming the difference between each pair of adjacent detectors, identifying the mode of the histogram and subtracting the integrated mode for each detector datastream, while demanding the average subtraction over the whole DPM field to be zero. These datastreams were then combined with the pointing information and subsequently gridded to a spatial matrix of  $3^\circ$  (in-scan)  $\times$   $2^\circ$  (cross-scan) with pixels of  $2.0$  in the cross-scan direction and respectively  $0.25$ ,  $0.25$ ,  $0.50$  and  $1.0$  in the scan direction in the 12, 25, 60 and  $100\ \mu\text{m}$  bands by using standard software (Deep Sky Co-add Observation Processor DSCO; Kopan, 1982). Detector data were co-added to each grid cell whose centre falls within the detector size. This grid matrix represents the infrared surface brightness in the four IRAS wavelength bands. Only non-filtered intensity grids were produced so that flux information is preserved. We obtained 41 individual DPM grids on the SMC in this way (see Table 2).

The second stage of the processing, done at Leiden Observatory, consisted of combining individual DPM grids, and obtaining a qualitatively and quantitatively good final product. First, quality checks brought to light that one of the SMC DPM grids (number 5851 in Table 2) has degraded pointing reconstruction. To get an equal coverage of each area of the SMC, eight other grids were left out. The remaining 32 grids then were used to obtain three combined map sets (in four wavelength bands) of the whole SMC (each map covers an area of  $4.3 \times 4.3$  with a grid spacing of  $0.25 \times 2.0$ ; the two map sets that have their scan direction in constant Right Ascension are denoted by NS and the map set with scan direction in constant Declination by EW; Table 2 also shows which grid numbers were combined into each map set). These combined maps were made using standard SDAS software (Deep Sky Grid Adding Processor DSGAD; Kopan, 1982). This first converts all individual grids to the same reference map and then adds all grids together weighting global noise for minimum variance and matching overlapping areas of individual grids.

The SMC is positioned at high ecliptic latitude so that there is little variation in the Zodiacal light emission over the maps. Nevertheless, some Zodiacal emission is still present and can be clearly seen on the IRAS  $16.5$  Skyflux images at levels of about 13 and 28 MJy/sr at 12 and  $25\ \mu\text{m}$ , and much less at 60 and  $100\ \mu\text{m}$  (about 5 MJy/sr). The galactic latitude of the SMC is  $-44^\circ$  so that the Galactic foreground, is weak (8 MJy/sr at  $100\ \mu\text{m}$ , much less at other wavelengths). At the 60 and  $100\ \mu\text{m}$  wavelengths the Galactic foreground cirrus gives more severe problems than the Zodiacal foreground because the Galactic foreground dust is colder. These large scale, relatively smooth foregrounds were removed in a somewhat arbitrary fashion by fitting a plane to map areas considered to be free of SMC emission. Discrete non-SMC sources, such as foreground stars, were not removed from the maps. Our zero-level correction removes most of the foreground emission but assumes a planar foreground, which is only a first order approximation of the foreground. In Section 3 we describe the uncertainties that are left in the map after the foreground removal.

To finally bring the IRAS AO (DPM) data to the current (IRAS November 1984 standard) calibration — the same calibration as the released primary IRAS products — we produced pixel-by-pixel scatterdiagrams of the DPM maps versus the Skyflux HCON-1 maps (the only one available at that time) at a resolution of  $9'$ . Because a pixel-to-pixel correlation was required here, the slope of the diagram yields the necessary correction factors to arrive at the November 1984 calibration; these factors have an estimated relative

uncertainty of about 10 % and correspond well to those communicated to us by Kopan (priv. comm.) obtained in a different manner using many more AOs on NGC 6543 (IRAS Primary Photometric Reference, positioned near the North Ecliptic Pole). The error of 10 % gives a good estimate of the reliability of the IRAS data on any point in the map. The correction factors are in principle affected somewhat by positional and flux errors in both the Survey derived and AO DPM derived maps. We have empirically corrected for most of the positional errors by determining the (Skyflux HCON-1)/(DPM AO) intensity ratios with a beam large compared to position uncertainties and applying small shifts to minimize scatter in the pixel-to-pixel correlation. This method was very succesful on the LMC; on the SMC severe striping in the Skyflux data made this method more difficult to use at 12 and 25  $\mu\text{m}$ , but the factors that we found did not differ much from those of Kopan, and therefore we used his factors in those wavelength bands.

Notes to Table 2:

a) For a description of names and abbreviations (Grid, SOP, OBS) we refer to IRAS (1985a) and IRAS (1986).

b) The field size of each observation is 3 degrees in the scan direction and 2 degrees in the cross-scan direction.

c) The scan direction is given by its position angle Pos.Ang (degrees NESM).

d) Map/Obs set 1 and 2 are scanned in the North-South direction, while Map/Obs set 3 is scanned East-West. The number of the set is identical to the number of the combined map in the text (see Section 2 and 3).

A dash in this column indicates that the grid was not used in the processing for various reasons.

In Figures 2, 3 and 4 we display all three Obs/Map sets.

e) Observation Id CG stands for Close Galaxies.

### 3. The maps of infrared radiation

Fig. 1 shows a  $100\ \mu\text{m}$  map of the SMC (and LMC) and their surroundings, constructed from Spline-I maps (van Albada *et al.*, 1985) by Braun, Walker and Deul at Leiden Observatory (taken from their collection of sky maps, see also Burton *et al.*, 1986). At the top the southern part of the Milky Way is visible (dust clouds associated with the Carina Arm at the top right, with peak intensities around  $5000\ \text{MJy/sr}$ ). The LMC is just below the centre ( $l = 280^\circ, b = -33^\circ$ ). The SMC ( $l = 304^\circ, b = -44^\circ$ ) is seen at the bottom left, with a peak in the SW-Bar of only  $42\ \text{MJy/sr}$ . The diffuse SMC emission is at a level of 11 and the Galactic foreground of  $8\ \text{MJy/sr}$ . From the figure it is clear that the Galactic infrared foreground at the position of the SMC is not very complex and easy to remove.

Table 3. Description of the SMC DPM-map characteristics.

Characteristic (Unit)	Wavelength band			
	12 $\mu\text{m}$	25 $\mu\text{m}$	60 $\mu\text{m}$	100 $\mu\text{m}$
Effective frequency ( $10^{12}\ \text{Hz}$ )	25	12	5	3
Bandwidth ( $\mu\text{m}$ )	7.0	11.2	32.5	31.5
Bandwidth correction ( $10^{12}\ \text{Hz}$ ) <sup>a)</sup>	13.48	5.16	2.58	1.00
Zero-magnitude flux density $f_\nu$ (0.0 mag) (Jy)	28.3	6.73	1.19	0.43
Point Source Conversion factor (Jy / $10^{-8}\ \text{Watt m}^{-2}\ \text{sr}^{-1}$ )	0.037	0.11	0.41	2.08
Positional accuracy (")	15	15	15	15
Nominal detector size ('x')	0.75 x 4.5	0.75 x 4.7	1.5 x 4.8	3.0 x 5.0
Resolution ('x') <sup>b)</sup>	0.9 x 6.4	1.1 x 6.4	2.0 x 6.4	3.8 x 6.4
Absolute calibration (%)	10	10	10	10
Median noise (MJy/sr) <sup>c)</sup>	0.096	0.097	0.12	0.20
( $10^{-8}\ \text{Watt m}^{-2}\ \text{sr}^{-1}$ )	1.3	0.5	0.3	0.2
Zero-level uncertainty (MJy/sr)	0.015	0.019	0.039	0.10
( $10^{-8}\ \text{Watt m}^{-2}\ \text{sr}^{-1}$ )	0.2	0.1	0.1	0.1
Stripe residuals (MJy/sr) <sup>d)</sup>	0.052	0.058	0.12	0.30
( $10^{-8}\ \text{Watt m}^{-2}\ \text{sr}^{-1}$ )	0.7	0.3	0.3	0.3
Sensitivity (MJy/sr) <sup>e)</sup>	0.3	0.3	0.4	0.6
( $10^{-8}\ \text{Watt m}^{-2}\ \text{sr}^{-1}$ )	4	2	1	0.5

Notes to Table 3:

a) Chester (priv. comm.).

b) The Gaussian resolution is given in arc-minutes (in-scan x cross-scan). One arcminute at the distance of the SMC (63 kpc) corresponds to 18 pc.

c) The value of the median noise is influenced somewhat by the extended emission of the SMC itself. The real detector noise is somewhat lower.

d) Higher stripe levels than the average level given in the table can occur.

e) The sensitivity indicates the intensity limits of Table 4. Note that the IRAS PSC sensitivity limits are 0.25, 0.25, 0.40, 1.00 Jy (see IRAS, 1985a).

**Figure 1.** IRAS Spline-I infrared map at  $100\ \mu\text{m}$  made at the Groningen Laboratory for Space research (van Albada *et al.*, 1985; Braun, Walker and Deul, *priv. comm.*) showing an area of  $50^\circ \times 50^\circ$  around the Magellanic Clouds with a resolution of about  $10'$ . Galactic 1950 coordinates are indicated. The infrared foreground can clearly be seen. Two extended infrared features (tidal arms) are in fact associated with HI at local Galactic velocities. Intensities between  $4$  and  $35\ \text{Watt m}^{-2}\ \text{sr}^{-1}$  are indicated by grey scales, with darker grey scales for higher intensities. Contours are at  $11, 14, 21, 70, 175, 350, 700, 1750, 3500, 5250 \times 10^{-8}\ \text{Watt m}^{-2}\ \text{sr}^{-1}$ .

Fig. 2, 3 and 4 show the IRAS DPM-maps of the whole SMC field. In these figures we indicate the boundaries of the coverage of the IRAS DPM observations. The NS and EW scanned maps are shown because the resolution in the scan direction is higher than the the cross-scan resolution; thus, the two (NS and EW) sets are complementary in terms of resolution. There is less diffuse emission present in the 12 and 25  $\mu\text{m}$  maps than in the other wavelength bands. In these maps the contrast between small, discrete sources and the diffuse more extended emission is much higher ( $\sim 40$ ) than at 60 or 100  $\mu\text{m}$  ( $\sim 10$ ). The coverage of the SMC is not complete in the SE, where the HII-region N 90 is just outside of the map. Because HII region N 3 is just at the edge at the SW, good fluxes cannot be obtained for this source. Special Co-adds of IRAS Survey data have been done centered on these two objects and are presented in Appendix A.

Detailed maps in four fields on the SMC are presented in Schwering and Israel (1988) and are available in digital form at the Centre de Données Stellaires (Astronomical Data Centre CDS) in Strasbourg, France.

All maps shown in this chapter are given in in-band intensities  $\int d\nu R_\nu I_\nu$  ( $\text{Watt m}^{-2} \text{sr}^{-1}$ ), with  $R_\nu$  the relative system response (see IRAS, 1985a; Table II.C.5 therein). To convert these values to specific intensities  $I_\nu$  ( $\text{Watt m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$ ) correction factors should be applied depending on the bandwidth (these factors are given in Table 3, assuming an intrinsic source spectrum  $f_\nu \propto \nu^{-1}$ , which is roughly correct for most dust clouds associated with HII regions:  $T_d \approx 40 \text{ K}$ ). For individual sources or positions, more accurate flux densities can be obtained by first determining the actual spectrum and then applying the relevant colour dependent correction (see IRAS 1985a and IRAS 1985b, Table VI.C.6 therein).

**Figure 2. Overall infrared maps of the Small Magellanic Cloud.**

Map set 1 (NS) of Table 2 is presented in equatorial coordinates for 1950. The maps are given in in-band intensities. All maps have sizes of  $4.3 \times 4.3$ . The coverage of the DPM-field is indicated by solid lines. Although not shown, the coverage differs somewhat in the four wavelength bands due to the location of detectors in IRAS's focal plane. See pages 20 – 21.

For the 12  $\mu\text{m}$  band grey scales range from 9 to 33, with darker grey scales for higher intensities. Contours are at 5, 10, 15, 20,  $50 \times 10^{-8} \text{ Watt m}^{-2} \text{sr}^{-1}$ .

For the 25  $\mu\text{m}$  band grey scales range from 9 to 33, with darker grey scales for higher intensities. Contours are at 2, 4, 6, 8, 10, 30, 50,  $100 \times 10^{-8} \text{ Watt m}^{-2} \text{sr}^{-1}$ .

For the 60  $\mu\text{m}$  band grey scales range from 9 to 58, with darker grey scales for higher intensities. Contours are at 1, 2, 4, 6, 8, 10, 15, 20, 40, 80,  $140, 200 \times 10^{-8} \text{ Watt m}^{-2} \text{sr}^{-1}$ .

For the 100  $\mu\text{m}$  band grey scales range from 9 to 58, with darker grey scales for higher intensities. Contours are at 0.5, 1, 2, 4, 6, 8, 10, 15, 20, 40,  $80 \times 10^{-8} \text{ Watt m}^{-2} \text{sr}^{-1}$ .

**Figure 3. Overall infrared maps of the Small Magellanic Cloud.**

Map set 2 (NS) of Table 2 is presented in an identical way as set 1 (NS) in Figure 2. The coverage of the DPM-field is indicated by solid lines. See pages 22 – 23.

**Figure 4. Overall infrared maps of the Small Magellanic Cloud.**

Map set 3 (EW) of Table 2 is presented in an identical way as set 1 (NS) in Figure 2. The coverage of the field by the DPM map is indicated by solid lines. See pages 24 – 25.

The estimated uncertainties in the DPM maps are given in Table 3. There are only minor differences in quality of the three different sets of maps. The noise (in MJy/sr) in the maps increases in the higher wavelength bands. Because the noise is based on map statistics, this is due to the increased extended emission of the SMC itself. The zero-level is also less well defined in those bands due to the extended emission. The sensitivity is based on reliable point sources that could be extracted from the maps. Just North of the SMC-Bar in map set 1, a bad detector scan makes that part of the map unusable, but as it falls completely outside the SMC it does not hamper the interpretation of the data.

## 4. The Infrared Source List in the SMC

### 4.1. The Source List

We searched the three sets of maps shown in Fig. 2, 3 and 4 for both resolved and unresolved discrete sources (Table 4) down to intensity levels of 5, 2, 1 and  $0.5 \times 10^{-8}$  Watt m<sup>-2</sup> sr<sup>-1</sup> at 12, 25, 60 and 100  $\mu$ m (four times the median noise level). Intensity peaks, backgrounds and source sizes were estimated and used to obtain flux densities. The extended diffuse SMC infrared emission is also interpreted as background, whenever it was close to the source. A size estimate was obtained using the nominal gaussian resolutions in the different bands. All wavelength bands and all three different map sets were searched separately. In a single wavelength band flux densities are about equal in the three maps, especially in unconfused regions (deviation of about 15 %). The data were then merged. The IRAS PSC positions are quoted in Table 4 whenever an unambiguous identification was made.

Table 4 contains the following information:

- Column 1: Sequential number. We recommend the name LI-SMC for these sources (Leiden IRAS-SMC).
- Column 2: The position of the source (1950). The Right Ascension is given in hours, minutes and seconds. If given in 0.1<sup>s</sup> the position and error are that of the IRAS PSC entry given in Column 12, otherwise they are taken from the maps with an error of 12<sup>s</sup>. The declination is given in degrees, arc-minutes and arc-seconds. If given in 1" the position and error are that of the IRAS PSC entry given in Column 12, otherwise they are taken from our maps and have an error of 1'.
- Column 3: 12  $\mu$ m intensity peak and background level (in  $10^{-8}$  Watt m<sup>-2</sup> sr<sup>-1</sup>). A dash indicates that the source is below the intensity level given in the text.
- Column 4: The same as Column 3 for the 25  $\mu$ m band.
- Column 5: The same as Column 3 for the 60  $\mu$ m band.
- Column 6: The same as Column 3 for the 100  $\mu$ m band.
- Column 7: The size of the source in  $\alpha(^{\circ}) \times \delta(^{\circ})$ . p denotes a source that cannot be discerned from a point source response. A semi-colon denotes an uncertain size. A dash indicates that no reliable size could be estimated because no FWHM could be determined.

Fig. 2.2. SMC 25  $\mu$ m DPM-map (set 1; NS).

Fig. 2.3. SMC 60  $\mu$ m DPM-map (set 1; NS).

Fig. 2.4. SMC 100  $\mu$ m DPM-map (set 1; NS).

Fig. 3.1. SMC 12  $\mu$ m DPM-map (set 2; NS).

Fig. 3.2. SMC 25  $\mu$ m DPM-map (set 2; NS).

Fig. 3.3. SMC 60  $\mu$ m DPM-map (set 2; NS).

Fig. 3.4. SMC 100  $\mu$ m DPM-map (set 2; NS).

Fig. 4.1. SMC 12  $\mu$ m DPM-map (set 3; EW).

Fig. 4.2. SMC 25  $\mu$ m DPM-map (set 3; EW).

Fig. 4.3. SMC 60  $\mu$ m DPM-map (set 3; EW).

Fig. 4.4. SMC 100  $\mu$ m DPM-map (set 3; EW).

- Column 8: Flux density of the source at  $12\ \mu\text{m}$  in Jy, assuming an intrinsic source spectrum  $f_\nu \propto \nu^{-1}$  (the same as for the released IRAS products; IRAS, 1985a). C denotes confusion with either background or other discrete sources and a semi-colon indicates an uncertain flux density. Flux densities are calculated using the size of Column 7. When the size could not be measured the point source response was assumed. Table 3 gives Point Source Conversion Factors to convert (Peak-Background)  $\text{Watt m}^{-2} \text{sr}^{-1}$  to Jy. The error in flux densities is assumed to be about 10 %, but somewhat higher at the lower intensity levels.
- Column 9: The same as Column 8 for the  $25\ \mu\text{m}$  band.
- Column 10: The same as Column 8 for the  $60\ \mu\text{m}$  band.
- Column 11: The same as Column 8 for the  $100\ \mu\text{m}$  band.
- Column 12: If the source is present in the IRAS PSC (IRAS, 1985a) and/or in the IRAS SSS (IRAS, 1985b) the name in that catalogue is given. A semi-colon indicates that the associated PSC or SSS entry is at a large distance from the source. An asterisk indicates that the association has been made for more than one source in the list.
- Column 13: The spectral type of the source. Spectrum type C is a typical cool dust spectrum (typical  $T_d \approx 30\ \text{K}$ ), peaking beyond  $100\ \mu\text{m}$ ; colour correction factors are of order 1.00, 0.95, 0.99, 1.00. Type W is a warm dust spectrum (typical  $T_d \approx 70\ \text{K}$ ), peaking between  $12$  and  $100\ \mu\text{m}$ ; colour correction factors are of order 1.03, 1.00, 1.00, 1.04. Type S is a stellar spectrum (typical blackbody of about  $5000\ \text{K}$ ); colour correction factors are of order 1.43, 1.40, 1.32, 1.09. A semi-colon indicates that the infrared spectrum is uncertain. Actual flux densities can be calculated from the quoted ones by dividing the latter by these colour correction factors (see IRAS, 1985a).
- Column 14: Comments information on identification in other catalogues.

Our source list contains 219 entries. In the area covered by the DPM fields 146 entries were found in the IRAS PSC, of which 138 could be identified unambiguously. Five PSC sources can be identified, but show some positional difference (about  $1.4'$ ). The remaining three PSC sources could not be identified on the DPM maps: IRAS 00515-7227, 01062-7210, 01098-7225, almost certainly because of confusion problems. The last ( $100$  and  $60\ \mu\text{m}$ ) source has a (second and correct,  $25\ \mu\text{m}$ ) IRAS PSC entry at  $1.5'$  distance (01095-7225). We believe that these two PSC entries are in fact the same source. The other two sources have reliable PSC flux densities at  $60\ \mu\text{m}$  only. They are probably the result of confusion in the SMC Bar (see below). IRAS 00296-7404 (HII region N 3) peaks just inside one DPM map and is detected at  $60$  and  $100\ \mu\text{m}$ . We left it out of the source list, because the coverage of the source is not very good. In total 33 PSC sources are clearly extended, and 60 are confirmed to be a point source. The source types in our list and in the PSC agree very well. Frequently, our procedure yields flux determinations where the PSC only gives upper limits.

All 13 entries in the IRAS SSS and inside the DPM fields were detected. Two of them (IRAS X0110-724 and X0112-735) are associated with more than one of our sources. The associations for IRAS X0110-724, X0115-737 and for X0123-736 are farther than  $3'$  away. Nine SSS sources have an association with an entry from the PSC; these must be sources

# II. Infrared observations of the SMC

with unresolved and extended components. The extended structure of the SMC at 60 and 100  $\mu$ m is complicated, and therefore sometimes does the SSS entry merely represent just one part of it. There are 72 new infrared sources in this source list, not included in the PSC nor in the SSS. The IRAS High Source Density Bin data (IRAS, 1985a) show that the condition of high source density exists at 100  $\mu$ m over the whole SMC and at 60  $\mu$ m in the SMC Bar. In these confused and high source density regions in the sky the IRAS PSC is constructed with the primary aim to be reliable, even when it means less complete. The majority of these new sources are point sources, and clearly show the incompleteness of the IRAS PSC in confused areas.

#### 4.2. Positions

The positions of the sources in the maps were compared with sources in the IRAS PSC. There was a good correspondence, that allowed us to use PSC coordinates for an unambiguous association. In the 12  $\mu$ m map the correspondence with the known SAO

star positions is very good (average deviation of  $15''$ ). We also compared the positions at a resolution of  $9'$  against the Skyflux HCON-1 maps. Compared to the Skyflux data there are small systematic position shifts of order of  $1'$  ( $\frac{1}{2}$  Skyflux-pixel size), but because those shifts are not present when we compare the DPM maps with the PSC, this indicates that the positional accuracy in the DPM maps presented here is significantly better than that in the Skyflux maps. Ground based near-infrared observations at La Silla (Israel *et al.*, 1988) indicate an overall mean accuracy of  $10''$  for IRAS point sources (PSC) in the Magellanic Clouds.

#### 4.3. Flux densities

We compared the flux densities from the DPM maps with those from the PSC (version 1.0, November 1984). This is a comparison of independent data obtained with the same instrument, but reduced in a different manner. At  $12$  and  $25\ \mu\text{m}$  we see a discrepancy at the low flux levels. The PSC fluxes are consistently higher below  $0.4$  Jy. The (known) flux overestimate in the PSC at low levels may be the explanation for this effect. At  $12\ \mu\text{m}$  the agreement is otherwise quite good, about the  $10\%$  quoted in Section 2. For extended sources and for relatively low quality sources in our list or in the PSC we find higher fluxes than in the PSC. At the other wavelength bands the number of such sources increases. The agreement with the high-quality sources is nevertheless very good. In the  $60$  and  $100\ \mu\text{m}$  bands, most sources have higher fluxes than in the PSC. The determination of the background is very important for calculating fluxes in these bands. The PSC filter works in the scan direction, while we compare different two-dimensional maps. It is not known to us how the PSC point source filter has interpreted the extended background structure of the SMC. We estimated the background for each source individually, and we believe that this visual investigation of the maps gives better results in confused regions than automated programs. A comparison of the fluxes of our maps and the IRAS SSS shows that some have very good agreement, but several show a lower flux on the DPM maps.

### 5. Identification of Sources

#### 5.1. Stars in the DPM fields

##### 5.1.1. Comparison with SAO stars

We have compared the Smithsonian Astrophysical Observatory Star Catalog (1966, henceforth the SAO Catalog) with our source database. Here we searched deeper (to  $10^{-8}$  Watt  $\text{m}^{-2}$   $\text{sr}^{-1}$ ) on averaged maps than in the infrared source list (Table 4) on the SAO positions. Detection of infrared emission on the known optical position depends on local noise and background (often  $3 - 4$  times less than the global noise given in Table 3). The area of the SMC covered by the DPM maps contains  $45$  SAO stars. We detect  $28$  of these (mainly at  $12\ \mu\text{m}$ ) and we have possible detections of five (for positional accuracy, see Section 4.2). The remaining  $12$  stars are below the local map sensitivity limits. In Table 5 we give the relevant data. Columns 1, 2 and 3 are taken from the SAO Catalog (version 1984). Columns 4 and 5 give the colour-corrected  $12$  and  $25\ \mu\text{m}$  flux densities as measured from the DPM maps. The low flux densities are more affected by noise etc. and

255778	8.6	F2	-	-	-	-	-	-	

## Notes to Table 5:

a) The 12 and 25  $\mu$ m flux densities in this table are colour-corrected (not in any of the other tables) by dividing the nominal flux densities by 1.43 and 1.40 (correction for a 5000 K black body) for stars with other temperatures these factors are about the same, see IRAS, 1985a).

b) Detection qualities at 12  $\mu$ m are good (+), medium (0) or poor (-).

c) See Section 5.1.1 in the text.

therefore have higher uncertainties. Column 6 gives the ratio  $f_{25\mu\text{m}}/f_{12\mu\text{m}}$  together with their uncertainties. If the spectrum of a star follows the Rayleigh-Jeans tail of the blackbody emission this ratio should be about 0.23. The ratio gives information about a possible 25  $\mu$ m excess relative to 12  $\mu$ m ( $f_{25\mu\text{m}}/f_{12\mu\text{m}} > 0.23$ ). The uncertainties are rather high because of the faint 25  $\mu$ m emission. Only one star (SAO 255735) may possibly

have a 25  $\mu\text{m}$  excess. Column 7 contains the  $m_V - m_{12}$  colour, which informs us about a possible 12  $\mu\text{m}$  excess (relative to the optical V band). We compared this column with the  $V - [12]$  colours listed in Table 3 of Waters *et al.* (1987) for the range of spectral types (A0 – K5). The stars are scattered within a 1 magnitude band around the values of Waters *et al.* (1987). Most of them have somewhat higher  $m_V - m_{12}$  values, but we do not find any star with a significant  $m_V - m_{12}$  excess due to the large scatter. The error in  $m_V - m_{12}$  is about 1.0 mag. On average these stars have an excess of  $0.3 \pm 0.2$  mag. Column 8 gives the identification of the SAO star in the infrared source list of Table 4. Out of the full sample of SAO stars fourteen can be found in that table (with intensities larger than  $3 \times 10^{-8}$  Watt  $\text{m}^{-2}$   $\text{sr}^{-1}$  at 12  $\mu\text{m}$ ). SAO 255752 is detected on the maps, but an optically weaker (non-SAO) star at about 2' East is brighter in the infrared (LI-SMC 198 in Table 4). Column 9 gives the quality of the detection of the star on the infrared maps, and Column 10 gives some remarks. Only SAO 255684 shows some possible 60  $\mu\text{m}$  emission. All eight G-type stars and thirteen out of fifteen K-type stars were detected at 12  $\mu\text{m}$ ; four out of six A-type stars and eight out of sixteen F-type stars were detected. There is no clear correlation between detection and visible magnitude in the whole SAO sample. But A-stars have been detected up to  $m_V \approx 8.4 \pm 0.5$ , F-stars up to  $m_V \approx 9.0 \pm 0.6$ , G-stars up to 10.0 and K-stars up to 9.1 magnitudes. Emission at 25  $\mu\text{m}$  is detected only from stars later than F5. All stars with 25  $\mu\text{m}$  emission also have 12  $\mu\text{m}$  emission. Most of these stars are probably Galactic foreground stars.

### 5.1.2. Comparison with Radcliffe SMC-stars

We also searched for emission from verified SMC stars (Feast *et al.*, 1960) and we detected emission in the direction of eight (out of 46). In the direction of another 18 we found possible weak emission. The Feast SMC stars are on average fainter than SAO stars by 3 or 4 magnitudes (the brightest being R 45 with  $m_V = 10.13$ ). They are the brightest SMC members (see Azzopardi and Vigneau, 1982). One star, R 10 is within a beam size from SAO 255715, and the emission is caused by the SAO star. R 8 is weakly indicated in the maps. R 14 is close to the HII region N 66 and probably we see emission from N 66 at 12  $\mu\text{m}$  rather than from the star. R 44 is associated with the HII region N 81 (HDE 7113), and we detect this HII region in the infrared. Four other stars (R 28, 29, 31, 32) are close to the H $\alpha$  nebulosity N 76 so that their detection likewise is not quite certain. More details about the comparison are given in Table 6. We conclude that the emission found is due to positional coincidence with other objects, and is not from the SMC stars itself. For twelve Radcliffe stars we mention possible positional infrared identifications in Table 4, of which only three have an S-type infrared spectrum. We conclude that these associations are also due to positional coincidences.

Because these stars are the brightest SMC stars we did not continue to look for emission from the whole list of 524 objects of Azzopardi and Vigneau (1982). Using the definition of 12  $\mu\text{m}$  magnitudes (see IRAS, 1985b; and Table 3) the IRAS sensitivity limit becomes  $m_{12} \approx 6$  mag. Waters *et al.* (1987) give a relation between intrinsic  $V - [12]$  colours and spectral type; for A-type stars  $V - [12]$  is about 0 mag and for K-type stars about 2.5 mag. Therefore the weakest A-type stars detectable by IRAS are of a visible magnitude  $m_V \approx 6$  mag and K-type stars have  $m_V \approx 10$  mag. Because the brightest SMC stars have

$m_V \approx 10.1$  mag, only stars with an infrared excess can be detected at a distance of the SMC (63 kpc).

Table 6. Radcliffe stars (Feast et al., 1960) in the SMC.

Notes to Table 6:

- a) Magnitudes followed by a V indicate that the star is variable, the average of the maximum and minimum magnitudes are given in those cases.  
b) Only associations 13, 19 and 89 from Table 4 have S-type infrared spectra, all others are associated to entries in Table 7 (HII regions). Infrared sources 156, 161, 162 and 187 have emission at other IRAS wavelength bands than 12  $\mu$ m.  
c) See Section 5.1.2 in the text.  
d) According to Feast et al. (1960) R44 corresponds to N81/HDE 7113. We find that their Table 2 coordinates are 9'N of N81. Here we used the N81 (HII region) coordinates (Henize, 1956).

### 5.1.3. Comparison with Late Type Giants

A comparison with the list of Carbon and late M-type stars (Blanco *et al.*, 1980) gives one possible detection. LI-SMC 54 (in Table 4) is situated 1'.5 West of the position of B 13 in the SMC Bar. This star is one of the list of Blanco *et al.* from which Cohen *et al.* (1981) detected near-infrared emission. The list contains 83 stars in the Bar and 56 in the Wing. Confusion in the SMC Bar may have resulted in this association, but may also be the reason that no others were detected. Another infrared source, LI-SMC 140, is situated 1' NE of the position of an irregular variable star HV 11423 (Payne-Gaposchkin, 1966). Near-infrared emission from this star was detected by Glass (1979). The 12  $\mu$ m flux density is about ten times higher than the 2.2 mag point of Glass shifted to the longer wavelengths via the Rayleigh-Jeans tail of a blackbody spectrum. If the association is correct the reason for this may be its (irregular) variability. HV 11423 is the brightest star in the K-band and is the most luminous M-type variable in the SMC (Glass, 1979).

### 5.1.4. Stars: Conclusion

In Table 4 there are 43 sources with an S-type infrared spectrum. Of these, fourteen are SAO stars. We looked at the other 29 objects on the photographic ESO-SRC Southern Sky Survey. Eighteen of them can be identified on those plates with stars (probably foreground; six fairly bright, twelve faint stars). Nine could not be identified because they are in the crowded SW-Bar. Most infrared spectra marked S in Table 4 (outside the Bar) have an optical identification, but often there is more than one star within a single beam so that these identifications are only tentative. We compared the list of infrared sources with an S-type spectrum with the list of SMC members of Azzopardi and Vignneau (1982). Six objects (infrared sources 19, 48, 96, 106, 107, 186) are within 2' from an SMC member in that list (respectively AZV 2\*, 36, 148, 164, 170, 438\*). These stars are A and B-type supergiants with  $m_V \approx 13$  mag. They are situated in the crowded SMC Bar, and therefore may be misidentified due to confusion. If the association is correct they must have an infrared excess, otherwise they would have stayed invisible at 12  $\mu$ m. Of the S-type infrared spectra there is one Galactic globular cluster NGC 362, and one SMC globular NGC 419 (Table 4; K 58 in Kron, 1956; L 85 in Lindsay, 1958) in our source list (see Section 5.3).

## 5.2. H $\alpha$ nebulosities in the SMC

A good overall agreement between H $\alpha$  emission regions and IRAS infrared emission was already noted by Schwering (1985). In Table 7 we present a more detailed comparison of the IRAS data with the H $\alpha$  catalogues of Henize (1956) and of Davies *et al.* (1976, henceforth DEM). The DEM catalogue contains 167 entries ranging in size from 0' to 30'. DEM entries 1 (N 3), 166 (N 90) and 167 are not covered by the IRAS DPM maps; they are discussed in Appendix A. About 70 % of all the bright H $\alpha$  nebulosities have clear infrared counterparts, 15 % have possible counterparts and the remaining 15 % do not show any clear infrared emission. For the fainter nebulosities the statistics are 50 % detected in the infrared, and 25 % possible detections, while the remaining 25 % does not show any infrared emission. We conclude that there is a higher detection probability in the infrared for the brighter HII regions. We detected infrared emission from about 70 % of the compact H $\alpha$  knots, while 60 % of the shells were detected.

166	N90	vb			Not covered by IRAS DPM-map.
167		f			Not covered by IRAS DPM-map.

## Notes to Table 7:

a) Associations 48, 54, 56, 106, 119 from Table 4 have S-type infrared spectra.

All other associated infrared sources have C-type or W-type infrared spectra.

b) See Section 5.2 in the text.

The whole SMC is covered by H $\alpha$  nebulosities (see DEM, 1976), and also by 60 and 100  $\mu$ m infrared radiation. From this comparison, we see that the discrete infrared sources correlate well with HII regions, and that HII regions are one of the main contributors to the infrared radiation in the SMC.

Table 8. Clusters in the SMC (Kron, 1956; Lindsay, 1958; Hodge and Wright, 1972), with infrared counterparts.

Notes to Table 8:

a) Only clusters which have possible infrared counterparts are given.

b) Only infrared associations 74, 134, 182 and 212 (in Table 4) were not previously included in Table 7 (HII regions). The other infrared associations have clusters and HII regions in a single beam, and thus are confused.

c) See Section 5.3 in the text.

### 5.3. Clusters in the SMC

We compared the list of star clusters of Kron (1956), Lindsay (1958) and of Hodge and Wright (1974) with our source list and the infrared maps. The clusters listed in Westerlund and Glaspey (1971) are not covered by the DPM maps. These four lists contain 220 clusters of sizes ranging from a few tenths of an arcminute to a few arcminutes. We searched deeper on the maps than in Table 4. In total we have 37 possible infrared detections of clusters, of which 20 have associations in Table 4. Sixteen of these infrared sources also have been associated to Table 7, showing the confusion with HII regions. Of these 37 possible

detections, two are very reliable. They coincide with blue globular clusters; K 35 (= L 54 = NGC 330) and K 58 (= L 85 = NGC 419) are detected at 12 and 25  $\mu\text{m}$ . These two are the brightest visual SMC globular clusters (van den Bergh, 1981). The remaining possible infrared associations have mainly 12  $\mu\text{m}$  emission and are very weak. Some are also seen at 60 and 100  $\mu\text{m}$ . Results of this comparison are given in Table 8.

We have also compared the globular clusters or compact groups from the list of 168 new clusters of Brück (1976; her types 1, 2 and 3). Only B 52 is such a cluster. All other new clusters are large loose groups, mainly blue or small blue clusters. There is an infrared source (LI-SMC 59) at about 1' SE but there is some extended emission present at this position in the SMC-Bar. LI-SMC 59 is also associated to HII region DEM 51 (see Table 7), which shows the confusion in the Bar. Recently Hodge (1986) added 213 new clusters in the SMC which brings the total number of cataloged clusters to 601. These new clusters are very small and faint and we do not expect much infrared emission from them.

#### 5.4. Supernova remnants in the SMC

We checked the list of six supernova remnants of Mathewson *et al.* (1983; their Table 2). All SNRs are smaller (0'5 – 5') than the IRAS beam size at 100  $\mu\text{m}$ . The first three remnants are situated in the crowded SW-Bar of the SMC. SNR 0045-73.4 coincides with extended emission between infrared sources LI-SMC 36 and 43 (see Table 4). SNR 0046-73.5 is located close to the edge of source 42, and SNR 0049-73.6 is situated in an infrared hole near sources 68 and 70. The last three are located in the NE part of the Bar. SNR 0101-72.4 can probably be associated with infrared source 160 (at 2'3 South) at about 6' from N 76. It is situated on infrared extended emission South of N 76. SNR 0102-72.3 is close to the East of N 76. There is some weak extended emission, but no clear correspondence with the remnant. SNR 0103-72.6 is situated 1'5 North of the peak of LI-SMC 169. All these associations are already given in Table 7 of the H $\alpha$  nebulosities. Table 9 summarizes this comparison.

Table 9. Known supernova remnants in the SMC (Mathewson *et al.*, 1983).

(1)	(2)	(3)	(4)	(5)
SNR Cat. number	Infrared Id <sup>a</sup>	SNR size arcsec	Detection quality	Remarks <sup>b</sup>

0049-73.6	2.9'SE of 68 3.0'NE of 70	110x 80	-	In SW Bar, in infrared hole.
0101-72.4	2.3'N of 160 2.7'N of 163 3.6'S of 156	98x 77	0	6'S of N76, on infrared extension. Probably 160.
0102-72.3	1.7'NE of 162 3.8'NE of 161	24x 24	-	In between N76 and N78.
0103-72.6	1.5'N of 169	292x187	0	On peak of 169.

Notes to Table 9:

a) All associations with Table 4 within 5' are given and all of them have C-type or M-type infrared spectra. All these associations have already been listed in Table 7 (HII regions).

b) See Section 5.4 in the text.

## 5.5. Planetary nebulae in the SMC

We compared the DPM infrared maps and the source list with the planetary nebulae identified by Sanduleak *et al.* (1978) and Sanduleak and Pesch (1981). Of their list of 34 nebulae numbers Sk 1, 2, 4, 20 and 29 are not covered by the IRAS DPM observations. The sizes of these nebulae are of order 1". Many of the nebulae are situated in extended infrared emission in the Bar and in the Wing. Seven nebulae (Sk 5, 6, 11, 15, 17, 19, 27) have probably infrared counterparts, and we have possible detections of six. We give results of the comparison in Table 10. Again we searched deeper than in Table 4. Only four nebulae have associations in Table 4. Sk 9 (with infrared LI-SMC 29) is positioned within one beam size of H $\alpha$  nebulosity N 13, therefore the association is not very reliable. Sk 19 is also close to an H $\alpha$  structure, but is probably real. A few sources show up in all four wavelength bands.

## Notes to Table 10:

- a) Association 29 (Table 4) with a C-type infrared spectrum was already associated to an HII region (see Table 7), the other three infrared associations have M-type infrared spectra.  
Except for nebulae 9 and 19 the nebulae are not disturbed by other prominent visible objects in the beam.
- b) References to nebulosities (N, see Henize, 1956) and emission-line objects (Ln, see Lindsay, 1961) are made.
- c) See Section 5.5 in the text.

Nebula Sk 11 is very bright in the infrared. Extrapolating its flux densities using the ratio  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  as a temperature measure ( $T_d \approx 50$  K) and assuming a dust emissivity with a  $\lambda^{-1}$  wavelength dependence, we find  $L_{\text{IR}} = 3.7 \times 10^4 L_{\odot}$ . This is high for a planetary nebula. The luminosity of the star is usually 3 to 10 times higher than the infrared luminosity (Pottasch, 1986). Paczynski's (1971) evolution tracks for planetary nuclei give a stellar luminosity of  $5 \times 10^4 L_{\odot}$  for the most luminous cases. For the Galactic planetary nebula NGC 6537 the IRAS PSC gives flux densities of 7.7, 58.3, 190 and 166 Jy at 12, 25, 60 and 100  $\mu\text{m}$ . An extrapolation of these IRAS flux densities (with  $T_d = 55$  K) gives  $L_{\text{IR}} = 2300 L_{\odot}$  (16 times less). Pottasch (1986) finds for 16 Galactic planetary nebulae values for  $L_{\text{IR}}/L_{\odot}$  of typically a few hundred. The extrapolation gives a good estimate of the infrared luminosity for a continuum spectrum. According to Pottasch (1986) line radiation can form a large fraction of the emission from average size nebulae in the IRAS survey bands and may even dominate the continuum in these bands, probably also at 60 and 100  $\mu\text{m}$  (Leene and Pottasch, 1986). If that is the case the infrared luminosity is an overestimate. If we assume a distance of 2.4 kpc for NGC 6537 (Gathier, 1984), a nebula with the same infrared brightness as NGC 6537 would have flux densities of 0.01, 0.08, 0.3 and 0.2 Jy in the IRAS bands at the distance of the SMC. This is about equal to our detection limits. For most identifications other than the brightest (Sk 11) we actually find flux densities of this order (see Table 10). Four nebulae have their infrared emission peak at 25 or 60  $\mu\text{m}$ , which is typical for planetary nebulae (see *e.g.* NGC 6537).

### 5.6. Dark clouds in the SMC

We compared the infrared data with the dark nebulae listed by Hodge (1974). In his paper about the LMC, Hodge (1972) discussed the uncertainties related to incompleteness of his list. These 45 dark clouds range in size from 1' to 6'. In the comparison we used positions from his Plate-I after we discovered that six nebulae (21, 30, 37, 40, 41, 45) differ from the positions in his Table 1. Results are listed in Table 11. The infrared emission at 60 and 100  $\mu\text{m}$  follows the nebulae in the SW-Bar very well. At the East side of the SW-Bar the infrared follows the dark clouds 29, 30, 32 and 33. All known dark nebulae are in the Bar and the Wing. Nineteen have an association in Table 4. Most clouds can be associated with an infrared feature but some (31, 39, 40, 43) are associated with an infrared minimum.

## 6. Conclusions

In the SMC DPM maps, 219 discrete sources were found; 143 of these are identified with sources in the IRAS Point Source Catalog (PSC). Sixteen sources correspond to sources in the IRAS Small Scale Structure Catalog (SSS). We found a total of 72 sources not listed in either of these catalogues. In many cases, we determine actual flux densities for sources while the PSC gives only upper limits. Most sources are associated with known HII regions and dark clouds in the SMC. At the positions of known objects in the SMC, we conducted deeper searches of the maps. The results are as follows.

Out of 45 SAO stars, we detected infrared emission from 28, and possibly five more. No cataloged stars in the SMC were identified with certainty, but 29 infrared, non-SAO

Table 11. Hodge (1974) dark clouds in the SMC.

## Notes to Table 11:

a) In the SW Bar region at 60 and 100  $\mu$ m the infrared contours follow Hodge's dark clouds numbers 1, 2, 3, 4, 5, 6, 7, 8, 10, 11, 12, 13, 14, 17. An infrared extension is visible East of the SW Bar corresponding to clouds 29, 30, 32, 33.

All associations (with Table 4) in the SW Bar are suspect due to confusion.

Cloud numbers 21, 37, and 40 have somewhat bad positions, numbers 30, 41 and 45 have completely wrong positions in Hodge's Table 1 compared to Plate I (corrected 1950.0 equatorial coordinates are given).

b) All associations have M-type or C-type infrared spectra. Infrared sources 63, 74, 81, 108, 130 were previously included in Table 7 (HII regions).

c) See Section 5.6 in the text.

sources with stellar-type infrared spectra were found, most of which have possible optical counterparts. One Galactic globular cluster (NGC 362) and two SMC globular clusters (NGC 330 and NGC 419) were also detected. Thirty-five open clusters have possible infrared counterparts. No clear correlation between supernova remnants and infrared emission was found. Infrared emission is seen towards seven, and possibly six more, planetary nebulae (out of 29). However, the majority of these objects is confused with other infrared emitting objects.

**Acknowledgements**

We wish to thank the following people: The SDAS team that supported the first reduction stage and assisted PS during his stay at the Jet Propulsion Laboratory; E. Kopan, P. Alphenaar, A. Vos and D. Hogeweg for writing the necessary software; Drs. H. Habing, J. Emerson and T. de Jong for scheduling the observations; Drs. H. Habing, W. Rice, R. Walterbos, R. Braun, A. van Genderen and H. Caspers for discussions. PS is grateful for financial support from the Space Research Organisation in the Netherlands (SRON), a subsidiary of the Netherlands Organization for Scientific Research (NWO) during his stay at JPL. We also want to thank the Astronomical Data Center at the NASA Goddard Space Flight Center for providing the SAO Catalog (version 1984) and the library of the Royal Observatory of Edinburgh for a prompt sending of a copy of an Occasional Report.

## Appendix A: Additions to the Infrared Source List

### A.1. Introduction

This infrared survey at 12, 25, 60 and 100  $\mu\text{m}$  covers the SMC with the exception of the outermost SE and SW parts, containing the HII regions DEM 1 (Davies *et al.*, 1976; N 3 in Henize, 1956), DEM 166 (N 90) and the H $\alpha$  filaments of DEM 167 (see Section 5.2). The latter object corresponds to the only known supergiant shell in the SMC (Meaburn, 1980). To complement the maps obtained from the Additional Observations, we derived IRAS (Co-added) maps using Survey data to cover the missing regions. Because these maps are produced from a different database than the DPM derived maps described in this chapter, we decided to discuss these maps in an Appendix.

### A.2. Observations and data reduction

The maps used in this Appendix are based on Co-added IRAS Survey data, specially produced at Leiden Observatory. We did not use the IRAS 16 $\times$ 5 Skyflux images (IRAS, 1985a) because of their lower resolution (4' to 6'). The Co-added Survey data give a resolution that is equal to the resolution of the Additional Observations (see Section 3). Input to the Co-add processor are the Boresight Pointing History File (BPHF) and Calibrated Reconstructed Detector Data (CRDD), calibrated to the May-1984 intermediate standard from the Leiden Observatory IRAS database.

First, we selected all IRAS Survey scans in an area of radius 1 $^\circ$  centered on the supergiant shell DEM 167 ( $\alpha_{1950} = 01^{\text{h}}28.0^{\text{m}}$ ,  $\delta_{1950} = -73^\circ35'$ ), and DEM 1 ( $\alpha_{1950} = 00^{\text{h}}29.6^{\text{m}}$ ,  $\delta_{1950} = -74^\circ04'3$ ). This was done by searching the Zodiacal Observation History File (ZOHF; IRAS, 1985a). In total 48 scans are covering the field of DEM 167 and 38 are covering the field of DEM 1; all these scans were used in the Survey Co-adds. The Zodiacal emission varies smoothly (see Skyflux's HCON-1, HCON-2 and HCON-3), and there is little variation in the infrared emission gradient with time at this high ecliptic latitude ( $\beta = -65^\circ$ ), allowing us to add all data from the three HCONs. Most scans have equal scan position angles to within 20 $^\circ$ . The average scan position angle (NESW) in the field of DEM 167 is 107 $^\circ$  and in the field of DEM 1 119 $^\circ$ . In the first field there are 6 scans with very different scan angles (about 158 $^\circ$ ), while in the latter field only one scan has a clearly different scan position angle (42 $^\circ$ ). The search radius of 1 $^\circ$  was chosen to obtain overlap between the DPM and Co-added maps so as to be able to compare the SMC extended emission and to compare discrete sources in the two independent map sets. The scan length selected from the CRDD is 32 seconds (at a scan rate of 3.85/sec) enough to cover a 2 $^\circ$  field.

The IRAS Survey scans were gridded onto a map of 2 $^\circ$  x 2 $^\circ$  centered on DEM 167, respectively DEM 1, by using the same software (DSO, DSGAD) as described in Section 2. The scans were added in the order of increasing distance from the field centre in order to have as much overlap in the scan-maps as possible in all subsequent additions. This overlap is important in identifying a better median offset to adjust individual scan-maps to the same intensity level. Because of the inclusion of HCON-3 scans (SOP > 425; 30 % of all scans) the median noise dropped by a factor of 2 relative to individual scan-maps.

To bring the calibration to the November-1984 calibration of IRAS (IRAS, 1985a; final product), we applied multiplication factors of 0.97, 0.98, 0.93 and 0.74 in the 12, 25, 60 and 100  $\mu\text{m}$  bands (Kopan, priv. comm.). These factors were checked against the behaviour of the eight IRAS calibration stars (see IRAS, 1985a), and NGC 6543 in a set of calibration Co-adds (Caspers, priv. comm.). As the low level infrared contours from the Co-added and the DPM maps connect very well, we did not attempt to further improve on the background correction.

### A.3. The maps of infrared radiation

The 12  $\mu\text{m}$  maps show some resulting stripes of 1' wide and 12' apart caused by the smaller edge detectors (see IRAS, 1985a). Special care was taken in the interpretation of positions affected by this artifact. These effects are not present in the other wavelength maps. Due to an error in the search for IRAS Survey scans, those covering only the outer edges were not accepted resulting in an increased noise at the NE and SW edges ( $\sim 10'$ ) of the field centered on DEM 167, and noisy and not-covered NE and SW edges of the same size in the field centered on DEM 1. Further characteristics of the Co-added maps are given in Table A.1. These maps are presented in Schwering and Israel (1988).

Table A.1. Description of the SMC Co-added map characteristics.

Characteristic (Unit)	Wavelength band			
	12 $\mu\text{m}$	25 $\mu\text{m}$	60 $\mu\text{m}$	100 $\mu\text{m}$
Median noise (MJy/sr) <sup>a)</sup>	0.04	0.04	0.03	0.05
( $10^{-8}$ Watt $\text{m}^{-2}$ sr $^{-1}$ )	0.6	0.2	0.09	0.05
Zero-level uncertainty (MJy/sr)	0.04	0.14	0.23	0.7
( $10^{-8}$ Watt $\text{m}^{-2}$ sr $^{-1}$ )	0.5	0.7	0.6	0.7
Stripe residuals (MJy/sr) <sup>b)</sup>	0.04	0.06	0.07	0.2
( $10^{-8}$ Watt $\text{m}^{-2}$ sr $^{-1}$ )	0.5	0.3	0.2	0.2
Sensitivity (MJy/sr) <sup>c)</sup>	0.3	0.3	0.4	0.6
( $10^{-8}$ Watt $\text{m}^{-2}$ sr $^{-1}$ )	4	2	1	0.5

Notes to Table A.1:

- a) The value of the median noise is influenced somewhat by the extended emission of the SMC itself, but not so much as in Table 3.
- b) Higher stripe levels than the average level given in the table can occur.
- c) The sensitivity indicates the intensity limits of Table A.2.

Comparing Table A.1 with Table 3 we note that the noise is about two times less at 12 and 25  $\mu\text{m}$  and four times less at 60 and 100  $\mu\text{m}$  compared to the AOs. This can be explained by the higher number of coverages (roughly ten for the Co-adds and about five for each AO set), but mainly by the lower amount of extended emission in the maps (especially at 60 and 100  $\mu\text{m}$ ). The zero-level is more uncertain (about five times), because no plane was fitted to the maps, but only an offset was subtracted. The stripe residuals are about the same.

In the 12 and 25  $\mu\text{m}$  maps some Zodiacal foreground emission is present in the form of a background slope in the maps of both fields with higher levels at the NW (about  $+10^{-8}$  Watt  $\text{m}^{-2}$   $\text{sr}^{-1}$ ) and lower at the SE edges ( $-10^{-8}$  Watt  $\text{m}^{-2}$   $\text{sr}^{-1}$ ). In the 60 and 100  $\mu\text{m}$  maps variations in the fields are caused by the extended emission of the SMC itself. No variation due to the Galactic foreground cirrus can be seen in these maps.

#### A.4. Additions to the Infrared Source List in the SMC

We have searched these maps in the same way as the DPM-maps in Section 4. Note that we have only a single map of these two fields in contrast to the three independent DPM-maps. Table A.2 contains the additions to the source list of Table 4.

We checked all sources from the DPM-maps (Table 4) and all sources from the IRAS PSC (IRAS, 1985a) and the IRAS SSS (IRAS 1985b). The IRAS PSC and SSS are based on the same data that were used in preparing the Co-added maps in this Appendix. All IRAS PSC entries in these two fields were confirmed by us, and are included in our source list. For all IRAS SSS sources infrared counterparts were found on the maps. In total we found thirty additional infrared sources in these fields of which fifteen are related to the IRAS PSC and SSS catalogs. Thus fifteen new infrared sources were found.

Table A.2. Additions to the SMC Infrared Source List.

### A.5. Identification of Sources

In this Appendix we are primarily concerned with the identification of all sources that were not already present in the DPM-maps (i.e. the area with  $\alpha > 01^h 25^m$  or with  $\alpha < 00^h 31^m$ ). For the identification of known objects we searched deeper than the infrared source list of Table A.2. None of the known supernova remnants (Mathewson *et al.*, 1983) nor any of the known dark clouds (Hodge, 1974) in the SMC are present in these areas.

#### A.5.1. Stars in the fields

##### A.5.1.1. Comparison with SAO stars

In Table A.3 we list the seven stars from the SAO Catalog (1966) that are present in these areas in the Co-added fields and their colour-corrected 12 and 25  $\mu$ m flux densities. None of these stars showed emission at 60 or 100  $\mu$ m.

Table A.3. SAO (1966) stars in the additional SMC fields.

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
SAO number	m V mag	Sp type	F <sup>a</sup> 12 $\mu$ Jy	F <sup>a</sup> 25 $\mu$ Jy	F <sup>a</sup> 25 $\mu$ / F <sup>a</sup> 12 $\mu$	m - m 12 mag	Infrared Id	Detection <sup>b</sup> quality	Remarks <sup>c</sup>
255653	8.0	G5	0.13:	0.16:	1.2 $\pm$ 1.0	2.2	220	0	On edge of Co-added map.
255665	8.0	G5	0.08	0.08:	1.0 $\pm$ 1.0	2.4		0	
255675	9.2	A	-	-	-	-		-	
255786	8.3	K0	0.16	0.16	1.0 $\pm$ 1.0	2.7	244	+	
255793	9.0	G5	-	-	-	-		-	
255805	9.3	--	-	-	-	-		-	Not covered by Co-added map.
255807	9.2	--	-	-	-	-		-	Not covered by Co-added map.

Notes to Table A.3:

a) The 12 and 25  $\mu$ m flux densities in this table are colour-corrected (see Table 5).

b) Detection qualities at 12  $\mu$ m are good (+), medium (0) or poor (-).

c) See Section A.5.1.1 in Appendix A.

##### A.5.1.2. Comparison with Radcliffe SMC-stars

Radcliffe stars (Feast *et al.*, 1960) R 47, 48, 49, which are positioned in the field of DEM 167, show no evidence for infrared radiation coming from these SMC stars. The other field does not contain Radcliffe stars that were not already discussed in Section 5.1.2.

#### A.5.2. H $\alpha$ nebulosities in the SMC

The main reason for Co-adding the IRAS Survey data was the failure of the IRAS DPM maps to cover the outermost edges of the SMC, especially HII regions DEM 1 (Davies *et al.*, 1976; N 3 in Henize, 1956), DEM 166 (N 90) and 167. The ring of diffuse filaments DEM 167 forms the only SMC supergiant shell, discovered by Meaburn (1980). The bright HII regions DEM 1 (infrared LI-SMC 239) and DEM 166 (LI-SMC 242) are

both detected in the infrared. N 1 of Henize corresponds to infrared source number 229. One field is centered on the supergiant  $H\alpha$  shell DEM 167, with a diameter of  $32'$ . In the infrared shell-like filaments are visible at 25, 60 and especially at  $100\ \mu\text{m}$  with its centre at  $1^{\text{h}}28.4^{\text{m}}, -73^{\circ}38'$  and a diameter of  $24'$ . The infrared emission follows the  $H\alpha$  quite well except in the North, where the infrared is about  $8'$  South of the  $H\alpha$  filaments. Infrared sources LI-SMC 240, 241, 245 and 246 are related to this supergiant shell.

### A.5.3. Clusters in the SMC

The area of interest to this Appendix in the DEM 167 field, contains no clusters from the list of Kron (1956), four (L 105, 107, 109, 110) from the list of Lindsay (1958), one (WG 1) from Westerlund and Glaspey (1971) and one (HW 86) from Hodge and Wright (1974). Only cluster L 105 shows possible infrared radiation; it coincides with LI-SMC 242 in the infrared source list (see Table A.2). Confusion with the  $H\alpha$  nebosity DEM 166 makes this identification uncertain; the infrared source is probably related to the HII region and not to the cluster. L 107 is positioned in extended emission of DEM 167.

The area of interest in the DEM 1 field, contains seven Kron clusters (K 1, 4, 5, 6, 8, 9, 10), eight Lindsay clusters (L 3, 4, 6, 7, 9, 12, 13, 15; the last seven are the same as the Kron clusters listed here) and three (HW 2, 3, 4) Hodge and Wright clusters. Of these only K 6 (= L 9) possibly shows weak infrared emission at  $12\ \mu\text{m}$  only ( $0.15\ \text{Jy}$ ).

### A.5.4. Planetary nebulae in the SMC

The field of DEM 167 contains no planetary nebulae of the list of Sanduleak *et al.* (1978) and Sanduleak and Pesch (1981), that were not already discussed in Section 5.5. In the field of DEM 1 there are two planetary nebulae (Sk 1 and 29) which are in the area of interest. Sk 1 corresponds in position to our source with LI-SMC 229 (in Table A.2) and to the  $H\alpha$  object N 1. This source peaks at  $25\ \mu\text{m}$  with  $0.2\ \text{Jy}$ , and there is some possible weak  $12\ \mu\text{m}$  emission ( $\sim 0.15\ \text{Jy}$ ). Sk 29 was not detected on the maps.

## A.6. Conclusions

In this Appendix we discuss sources on the infrared maps at 12, 25, 60 and  $100\ \mu\text{m}$  of the outermost SE and SW corners of the Small Magellanic Cloud. We found 30 infrared sources, which brings the total of infrared sources in and around the SMC to 249. In the areas that were searched all IRAS Point Sources (PSC) were detected and all IRAS Small Scale Structure (SSS) entries have related infrared sources. Fifteen sources are new detections. We identified the infrared sources where possible. Three foreground SAO stars were detected in these fields; no Radcliffe SMC-stars yielded a detection.  $H\alpha$  nebulosities DEM 1, 166 and 167 (a supergiant shell) were all detected in the infrared. The cluster K 6 (L 9), and the planetary nebula Sk 1 (N 1) are possible detections.

## Chapter III

### INFRARED OBSERVATIONS OF THE LARGE MAGELLANIC CLOUD

#### Summary

Results of IRAS pointed observations in four infrared wavelength bands (12, 25, 60 and 100  $\mu\text{m}$ ) on the Large Magellanic Cloud are presented. Maps are shown with orthogonal scan directions and a source list containing 1823 infrared sources is extracted from the data. Comparison with the IRAS Point Source Catalog (PSC) shows that twenty-eight entries in this catalogue are spurious. We confirm all 49 entries in the IRAS Small Scale Structure Catalog (SSS) in the LMC. We found 802 new infrared sources, not included in either the PSC or in the SSS. Our LMC infrared source list and the infrared maps are compared to other object lists. We identified 57 SAO stars, three LMC globular clusters and detected infrared emission from the direction of thirteen planetary nebulae. We detected infrared emission from four Radcliffe LMC-stars and five out of ten small size supernova remnants. In general there is a good correlation of infrared emission with the distribution of HII regions and dark clouds. A list of sources and comparison results from infrared maps of seven additional fields at the Northern and Western edges of the LMC are presented in an Appendix.

#### 1. Introduction

The Magellanic Clouds are the closest galaxies in the Local Group (Humphreys, 1984). They are our first extragalactic beacon and hence are important for a variety of studies related to galactic structure and to global properties of much more distant galaxies. For this reason it is important to relate their detailed characteristics to their global properties.

A summary of infrared surveys on the Magellanic Clouds has been given by Schwering and Israel (1988a; Chapter II). These surveys are supplemented by data obtained from the IRAS satellite; however, the published official IRAS data (IRAS, 1985a) have two weaknesses: in confused areas such as the Magellanic Clouds the point source data are not completely reliable, and the 16 $\times$ 5 extended emission infrared maps have a resolution of only 4' – 6'.

In Chapter II we presented infrared maps and an infrared source list for the Small Magellanic Cloud (SMC). In this chapter we continue with the Large Magellanic Cloud (LMC). Thus we present maps at the full IRAS resolution (ranging from 1'.1 at 12  $\mu\text{m}$  to 4'.3 at 100  $\mu\text{m}$ ) as well as a list of all sources identifiable in these maps. Some results of preliminary analysis were given by Schwering (1985, 1987).

## 2. Observations and data reduction

The observations presented in this chapter were obtained with the IRAS satellite as part of the AO program carried out with the IRAS survey array. A full description of the instrument array, the survey and data processing can be found in the IRAS Explanatory Supplement (IRAS, 1985a). A description of the AO program and a list of all rasterscan AOs observed by the IRAS satellite of many different objects are given in "A User's Guide to IRAS Pointed Observation Products" (IRAS, 1986).

There is a variety of pointed observations on the LMC (see Israel and Schwering, 1986), but Deep Sky Mapping (DPM) observations are the only ones covering the entire LMC in a regular manner and are therefore suited for a study of the whole LMC. The maps presented here are thus based on the DPM observations alone (see also Chapter II). The DPM observations were made in the months of June/July and September/October 1983, and are summarized in Table 1. For a description of the DPM observing mode see Chapter II.

As in the case of the LMC, two separate sets of DPM observations were made with almost orthogonal scanning directions: approximately EW and NS. This was possible because the LMC is close to the South Ecliptic Pole ( $\beta_{LMC} = -86^\circ$ ), so that observations obtained three months apart yielded the required orthogonal scanning directions. Due to the rectangular form of the IRAS survey detectors (largest size in the cross-scan direction) the resolution is highest in the scan direction (time-resolution), so that these two sets of data supply us with maximum resolution in both directions. In June and July the LMC was scanned EW (average position angle of the scan direction  $90^\circ$ ; observations set 1 EW in Table 1) in a double coverage. In September and October (three months later) the LMC was scanned NS ( $185^\circ$ ; set 2 NS) with double coverage. Because of the large size of the LMC compared to the area covered by a single DPM observation every LMC-coverage consists of sixteen differently pointed observations. Another observation was made in June/July and three more in September/October which were processed and later deleted for reasons of uniformity.

The reduction of the AOs was done in two stages and is explained in Chapter II. We obtained 68 individual DPM grids on the LMC (see Table 1). To get identical coverage of each area of the LMC, four grids were left out. The remaining 64 grids then were used to obtain two combined map sets (in four wavelength bands) of the whole LMC (each map covers an area of  $8.5 \times 8.5$  with a grid spacing of  $0.50 \times 2.0$ ; the two map sets that have their scan direction in constant Right Ascension are denoted by NS and the map set with scan direction in constant Declination by EW; Table 1 also shows which grid numbers were combined into each map set).

As the LMC is positioned near the South Ecliptic Pole there is little variation in the Zodiacal light emission over the maps. The galactic latitude of the LMC is  $-33^\circ$ . At the 60 and 100  $\mu\text{m}$  wavelengths the Galactic foreground cirrus creates more of a problem than the Zodiacal foreground, because it has a lower colour temperature. In Chapter II we have shown a 100  $\mu\text{m}$  map of the Magellanic Clouds and their surroundings (Fig. 1 therein). From that figure it is clear that, even at this relatively high galactic latitude, the Galactic infrared foreground in the direction of the LMC is complex. As was discussed by Israel and Schwering (1986) and by McGee *et al.* (1986) prominent infrared filaments are associated with Galactic neutral hydrogen, leading to complications in the foreground removal. The

large scale, relatively smooth foreground was removed by fitting a plane to map areas considered to be free of LMC emission. Our zero-level correction removes most of the foreground emission but assumes a planar shape, which is only a first order approximation to the actual foreground. Hence, some small-scale structure not belonging to the LMC and discrete non-LMC sources will be left. In Section 3 we describe the uncertainties that are left in the map. The final calibration is explained further in Chapter II.

## Notes to Table 1:

- a) For a description of names and abbreviations (Grid, SOP, OBS) we refer to IRAS (1985a) and IRAS (1986).  
b) The field size of each observation is 3 degrees in the scan direction and 2 degrees in the cross-scan direction.  
c) The scan direction is given by its position angle Pos. Ang (degrees NESH).  
d) Map/Obs set 1 is scanned in the East-West direction, while Map/Obs set 2 is scanned North-South. The number of the set is identical to the number of the combined map in the text (see Sections 2 and 3).  
A dash in this column indicates that the grid was not used in the processing for reasons of uniformity.  
In Figures 1 and 2 we display both Obs/Map sets.  
e) Observation Id CG stands for Close Galaxies.

### 3. The maps of infrared radiation

Fig. 1 and 2 show the IRAS DPM maps of the whole LMC field. In these figures we indicate the boundaries of the coverages of the IRAS DPM observations. These figures show detailed contour/grey scale representations of both DPM-maps at full IRAS resolution. We show both the NS and EW sets because the resolution in the scan direction is higher than the cross-scan resolution; thus, the two (NS and EW) sets are complementary in terms of resolution. There is less diffuse emission present in the 12 and 25  $\mu\text{m}$  maps than in the other wavelength bands; this is similar to the situation in the SMC. In these maps the contrast between small, discrete sources and the diffuse more extended emission is much higher than at 60 or 100  $\mu\text{m}$ . All maps shown in this chapter are given in in-band intensities (see also Chapter II).

Table 2. Description of the LMC DPM-map characteristics.

Characteristic (Unit)	Wavelength band			
	12 $\mu\text{m}$	25 $\mu\text{m}$	60 $\mu\text{m}$	100 $\mu\text{m}$
Effective frequency ( $10^{12}$ Hz)	25	12	5	3
Bandwidth ( $\mu\text{m}$ )	7.0	11.2	32.5	31.5
Bandwidth correction ( $10^{12}$ Hz) <sup>a)</sup>	13.48	5.16	2.58	1.00
Zero-magnitude flux density $f_\nu$ (0 mag) (Jy)	28.3	6.73	1.19	0.43
Point Source Conversion factor (Jy / $10^{-8}$ Watt $\text{m}^{-2}$ $\text{sr}^{-1}$ )	0.037	0.11	0.41	2.08
Positional accuracy (")	15	15	15	15
Nominal detector size('x')	0.75 x 4.5	0.75 x 4.7	1.5 x 4.8	3.0 x 5.0
Resolution ('x') <sup>b)</sup>	1.1 x 6.9	1.1 x 6.9	2.1 x 6.9	4.3 x 6.9
Absolute calibration (%)	10	10	10	10
Median noise (MJy/sr) <sup>c)</sup>	0.096	0.097	0.16	0.6
( $10^{-8}$ Watt $\text{m}^{-2}$ $\text{sr}^{-1}$ )	1.3	0.5	0.4	0.6
Zero-level uncertainty (MJy/sr)	0.015	0.097	0.39	1.0
( $10^{-8}$ Watt $\text{m}^{-2}$ $\text{sr}^{-1}$ )	0.2	0.5	1.0	1.0
Stripe residuals (MJy/sr) <sup>d)</sup>	0.15	0.3	0.8	2.0
( $10^{-8}$ Watt $\text{m}^{-2}$ $\text{sr}^{-1}$ )	2.0	1.5	2.0	2.0
Sensitivity (MJy/sr) <sup>e)</sup>	0.3	0.3	0.4	0.6
( $10^{-8}$ Watt $\text{m}^{-2}$ $\text{sr}^{-1}$ )	4	2	1	0.5

Notes to Table 2:

- a) Chester (priv. comm.); assuming  $f_\nu \propto \nu^{-1}$ .
- b) The Gaussian resolution is given in arc-minutes (in-scan x cross-scan). One arcminute at the distance of the LMC (53 kpc) corresponds to 15 pc.
- c) The value of the median noise is influenced by the extended emission of the LMC itself, especially at 60 and 100  $\mu\text{m}$ . The real detector noise is somewhat lower.
- d) Higher stripe levels than the average level given in the table can occur.
- e) The sensitivity indicates the intensity limits of Table 3. Note that the IRAS PSC sensitivity limits are 0.25, 0.25, 0.40, 1.00 Jy (see IRAS, 1985a).

The estimated uncertainties in the DPM maps are given in Table 2. There are only minor differences in quality of the two different sets of maps. The median noise (in MJy/sr) in the maps increases in the 60 and 100  $\mu\text{m}$  wavelength bands due to the increased extended emission of the LMC itself. The zero-level is also less well defined in those bands due to the complicated foreground emission. The sensitivity is based on reliable point sources that could be extracted from the maps and is roughly identical to the IRAS PSC sensitivity limit. The area of map set 1 (EW scanning), between the Greater 30 Doradus Region and the Bar, are influenced by a bad scan area (at the SE end of the Bar). This area has a relatively high degree of damage at 12 and 25  $\mu\text{m}$  and has enhanced noise at 60 and 100  $\mu\text{m}$ . Map set 1 also contains some radiation hits.

There are some differences in the data quality of these maps with the quality of the SMC map data. The higher median noise at 60 and especially at 100  $\mu\text{m}$  in these maps is caused by the extended emission of the LMC. The zero-level is less accurate by a factor of ten at 60 and 100  $\mu\text{m}$  due to the (uncertain) Galactic foreground; also at 25  $\mu\text{m}$  there is a larger uncertainty. The stripe-uncertainty level is roughly five times higher than in the SMC. The infrared extended emission of the LMC, which fills a large fraction of the maps, makes the determination of these map uncertainties less reliable than for the maps of the SMC.

Maps in sixteen fields on the LMC are given by Schwering and Israel (1988b) and are available in digital form at the Centre Données Stellaires (Astronomical Data Centre CDS) in Strasbourg, France. Maps that represent the infrared emission from the Northern and Western-edges of the LMC have been analysed in Appendix A.

**Figure 1.** Overall infrared maps of the Large Magellanic Cloud of map set 1 (EW) are given in equatorial coordinates for 1950. The maps are given in in-band intensities. All maps have sizes of  $8^\circ 0' \times 8^\circ 0'$ . The coverage of the field by the DPM EW-scanned maps is indicated by solid lines. Although not shown, the coverage differs somewhat in the four wavelength bands due to the location of detectors in IRAS's focal plane. See pages 56 – 57.

In the 12  $\mu\text{m}$  map grey scales range from 9 to 33, with darker grey scales for higher intensities. Contours are at 5, 10, 20, 40, 100, 200, 500, 1000,  $2000 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ . The overlap of neighbouring fields is roughly  $7'$ .

In the 25  $\mu\text{m}$  map grey scales ranging from 9 to 33, with darker grey scales for higher intensities. Contours are at 2, 6, 10, 20, 40, 100, 200, 500, 1000,  $2000 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ .

In the 60  $\mu\text{m}$  map grey scales ranging from 9 to 58, with darker grey scales for higher intensities. Contours are at 2, 6, 10, 20, 40, 100, 200, 500, 1000, 2000, 3000, 4000, 5000,  $6000 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ .

In the 100  $\mu\text{m}$  map grey scales ranging from 9 to 58, with darker grey scales for higher intensities. Contours are at 2, 6, 10, 20, 40, 100, 200, 500, 1000,  $2000 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ .

**Figure 2.** Overall infrared maps of the Large Magellanic Cloud of map set 2 (NS). The maps are in an identical representation as Fig. 1. See page 58 – 59.

#### 4. The Infrared Source List in the LMC

We searched the two sets of maps shown in Fig. a and 2 (and of Schwering and Israel, 1988b) for discrete sources down to intensity levels of 5, 2, 1 and  $0.5 \times 10^{-8}$  Watt m<sup>-2</sup> sr<sup>-1</sup> at 12, 25, 60 and 100  $\mu$ m (respectively 4, 4, 3 and 1 times the median noise level in the maps). Intensity peaks, backgrounds and source sizes were estimated and used to obtain flux densities. The diffuse LMC infrared emission is also interpreted as background, whenever it was close to the source. A size estimate was obtained using the nominal gaussian resolutions in the different bands. All wavelength bands and both different map sets were searched separately. In a single wavelength band flux densities are about equal in the two maps, especially in unconfused regions (deviation of about 20 %). The data were then merged. The IRAS PSC positions are quoted whenever an unambiguous identification was made. The source list is presented in Table 3. We recommend the use of the following names for sources in the list: LI-LMC (Leiden IRAS-LMC).

The LMC source list contains the same information as the SMC source list of Chapter II (Table 4 therein; see description). Our LMC source list contains 1823 entries. 1011 correspond to IRAS PSC sources, or can be identified with PSC sources with slight ( $< 3'$ ) positional differences. Twenty-eight PSC sources could not be identified on the DPM maps. These spurious sources are listed in Table 4. The reason for most sources is confusion with close neighbours or with the extended emission. The source (spectral) types (as defined in Chapter II) in our list and in the PSC agree quite well. The source list contains 1095 (60 %) sources with a C-type spectrum (cool dust spectrum), 475 (26 %) sources with a W-type (warm dust spectrum) and 253 (14 %) with a S-type spectrum (stellar spectrum). Frequently, our procedure yields flux determinations where the PSC only gives upper limits, especially at 60 and 100  $\mu$ m.

All 49 entries in the IRAS Small Scale Structure Catalog (IRAS SSS; IRAS, 1985b) that fall within the boundaries of the DPM fields were detected. Two of them (IRAS X0447-672 and X0509-685) are associated with more than one of our sources (both with one PSC and one non-PSC source). Forty-one SSS sources have an association with an entry from the PSC catalogue; these must be sources with unresolved and extended components. There are 802 new infrared sources in this source list, not included in the PSC nor in the SSS. The IRAS High Source Density Bin data (IRAS, 1985a) show high source densities at 100  $\mu$ m in the whole LMC; at 60 and 100  $\mu$ m over the face of the LMC; 25, 60 and 100  $\mu$ m in the Bar and the 30 Doradus region; and at all four wavelength bands in the 30 Doradus region. In these confused and high source density regions in the sky the IRAS PSC is constructed with the primary aim to be reliable, even when it means less complete. The majority of these new sources are likely to be point sources, and clearly show the incompleteness of the IRAS PSC in confused areas. The positional uncertainties of these sources are about the same as the uncertainties described in Chapter II.

# III. Infrared observations of the LMC

05467-6712	60,100	Confusion.
05482-6427	60	Confusion.
05496-6933	100	Confusion.
05570-6722	25	Confusion.
05585-7013	12	Only 0.26 Jy in IRAS PSC.

Note to Table 4:  
a) Except for 05100-6629, 05353-7026, 05570-6722 and 05585-7013 all unconfirmed IRAS Point Sources are confused.

## 5. Identification of Sources

### 5.1. Stars in the DPM fields

#### 5.1.1. Comparison with foreground stars

We have compared the Smithsonian Astrophysical Observatory Star Catalog (1966, henceforth the SAO Catalog) with our source database. For the comparisons we used maps obtained by averaging the two map sets with orthogonal scan directions, resulting in a somewhat higher signal-to-noise ratio and the special form of the point spread function makes point sources easier to recognize. On the SAO positions we have searched the maps deeper (to  $10^{-8}$  Watt m $^{-2}$  sr $^{-1}$ ) than for the infrared source list (Table 3). Detection of infrared emission on the known optical position depends on local noise and background (on these maps often three times less than the median noise given in Table 2).

The area of the LMC covered by the DPM maps contains 163 SAO stars. We detect 57 of these (with good detection quality at 12  $\mu$ m) and we have possible detections of 43 (with medium or poor detection quality). The remaining 63 stars are below the local map sensitivity limits. In Table 5.A, similar to Table 5 in Chapter II, we give the results of the comparison. Nine stars show possible 60 or 100  $\mu$ m emission, these are confused with HII regions. The detection statistics for the different stellar spectral types is given in Table 5.B. There is no clear correlation between detection and visible magnitude in the whole SAO sample. Except for G-type stars the visual detection limits are very similar to the ones found for the SMC foreground stars. These limits indicate that for the same infrared sensitivity later type stars are observed to lower visual magnitudes, as could be expected from their colours. Stars that have 25  $\mu$ m emission also have 12  $\mu$ m emission. Most of these SAO stars are probably Galactic foreground stars (but *e.g.* SAO 249329 corresponds to 30 Doradus).

Two infrared sources are associated to Variable Stars (Kukarkin *et al.*, 1969, 1970, 1971): LI-LMC 324 (RX Dor) and 1811 (RU Men, no LMC-member); three infrared sources related to Suspected Variable Stars (Kukarkin *et al.*, 1981) are: LI-LMC 130 (01777; M0 star; also SAO 249138), 1748 (02693, B6; also SAO 249368), 1820 (02830, M3); infrared source LI-LMC 1077 is associated to Cool Carbon Star 363 (Stephenson, 1973). A search through the AFGL Catalog (Price and Walker, 1976) has given us another foreground star identification: HV 884 (Feast *et al.*, 1980) corresponds to the S-type infrared source LI-LMC 324.

#### 5.1.2. Comparison with Radcliffe LMC-stars

We also searched for emission from verified LMC stars (Feast *et al.*, 1960) and we detected emission in the direction of several. The Feast LMC stars are on average fainter than SAO stars by 3 or 4 magnitudes (the brightest, with the exception of the 30 Doradus core, being R 76 with  $m_V = 9.11$ ). Details are given in Table 6. In most cases there is confusion with HII regions.

Some Radcliffe stars show clear infrared emission: R 126, is the only star with a S-type infrared spectrum, may be showing emission from the star itself or more likely an infrared excess; two stars, R 66 and R 71 show emission from a warm dust shell (see Stahl *et al.*, 1983; Wolf and Zickgraf, 1986). The brightest LMC member, R 76 also shows 25 and

Table 5.A. SAO (1966) stars in the field of the LMC.

## Notes to Table 5.A:

- a) The 12 and 25  $\mu$ m flux densities in this table are colour-corrected (unlike those in any of the other tables) by dividing the nominal flux densities by 1.43 and 1.40 (correction for a 5000 K black body) for stars with other temperatures these factors are about the same; see IRAS, 1985a).  
For possible 60 or 100  $\mu$ m flux densities of these stars we refer to Table 3. Note that colour correction factors should be applied to the flux densities in that table (division factors of 1.32 and 1.09 resp.).
- b) All associated infrared Id's have an S-type infrared spectrum, except for Id's 762 and 1104 with a C-type spectrum and Id's 585, 1076 and 1081 with a W-type spectrum. All associated infrared Id's are within 1' of the SAO star.  
Three associations (164, 1076 and 1469) are also associated to HII regions (see Table 7); these are thus confused.
- c) Detection qualities at 12  $\mu$ m are good (+), medium (0) or poor (-).
- d) See Section 5.1.1 in the text.

Table 5.B. Statistics of observed SAO spectral types.

(1)	(2)	(3)	(4)	(5)	
Spectral <sup>a</sup> type	Number of observed stars	Number of detected stars + 0	Visual detection limit (mag.)	Average m - m V 12	
O	1	0	1	9.3	6.6
B	4	2	0	6.7±0.5	-0.4±0.0
A	40	5	13	8.2±0.5	2.2±0.8
F	36	8	7	8.5±0.4	2.0±0.9
G	30	8	7	8.6±0.2	2.4±0.4
K	40	29	8	9.1±0.1	2.8±0.7
M	4	4	0	> 9.3	4.8±0.8

## Note to Table 5.B:

- a) One star of Peculiar type has not been detected.  
Three out of six stars without a spectral classification in SAO (1966) have been detected.  
The O-type star has a C-type infrared spectrum and shows strong 60 and 100  $\mu$ m emission, showing cool dust emission.  
The centre of 30 Doradus (SAO 249329) has an S3 type spectrum, with cool dust emission.

Table 6. Radcliffe stars (Feast et al., 1960) in the LMC.

Notes to Table 6:

- a) Radcliffe star numbers 1 to 50 are members of the SMC and are discussed in Chapter II.  
b) Magnitudes followed by a V indicate that the star is variable, the average of the maximum and minimum magnitudes are given in those cases. If no visual magnitude is available in Feast *et al.* (1960) the average photographic magnitude (mpg) is given in column 7.  
c) This table contains a 12  $\mu$  flux density only, for the 25, 60 and 100  $\mu$  flux densities we refer to Table 3.  
d) Only association 1413 from Table 3 has an S-type infrared spectrum.  
Twenty infrared associations which have also been referred to Table 7 (HII regions) have been denoted in the remarks in column 7. Clearly these objects are confused.  
e) See Section 5.1.2 in the text.

60  $\mu$ m emission indicating dust shell emission (like Glass, 1984; no 12  $\mu$ m emission was detected from this star). Nineteen other Radcliffe stars show some possible emission. Stars R 93, 94 and 95 are within 0'5 of each other, and form an extension on the infrared maps at 12 and 25  $\mu$ m to HII region N 43. R 94 is the brightest LMC member in JHKL (Glass, 1984) and was not detected by Glass at 10  $\mu$ m.

Because these stars are the brightest LMC stars we did not continue to look for emission from other LMC-stars (see Section 5.1.3). Using the reasoning of Chapter II and looking at the detection limits for various spectral types of SAO stars (Section 5.1.1) LMC-stars, which have  $m_V > 9.1$ , can be detected at the distance of the LMC (53 kpc) only if they have an infrared excess.

### 5.1.3. Comparison with LMC Late Type Giants

A comparison of the infrared sources of Table 3 with the list of 288 Carbon and late M-type stars (Blanco *et al.*, 1980) gives three possible detections: LMC BW 9 (infrared source LI-LMC 465), BW 50 (LI-LMC 503) and O 86 (LI-LMC 992). These infrared sources have C-type infrared spectra and the associations are not completely certain.

Some other sources that show possible infrared emission are: HD 268743 (LI-LMC 243), the LMC-Cepheid HV 2294 (LI-LMC 432) and HD 34664 (LI-LMC 642). For the last one Glass (1984) detected 10  $\mu$ m emission from circumstellar dust. However, these associations are not completely certain.

LI-LMC 1022 (C-type) is 1' N of the 1979 Gamma Ray Burst GRB 03/05/79 (Apparao and Allen, 1982), which might possibly be a M-type star. Entries numbers LI-LMC 181 and 1341 (both W-type) correspond to the two luminous evolved LMC stars with thick dust shells found by Elias *et al.* (1986).

Table 7. Infrared emission from H-alpha Emission Nebulae in the LMC (Davies et al., 1976; Henize, 1956).

(1)	(2)	(3)	(4)	(5)	(6)
DEM Id	Henize Id	Intensity of H-alpha	Infrared Id	Detection quality	Remarks <sup>a</sup>

132a	N119 (part)	b	789	+	Shell on infrared complex in Bar.
132b	N119 (part)	b	807,811	+	In Bar. Apparently associated with DEM 132a.
133	N121	fb		-	In Bar, at edge of infrared emission complex.
134	N120A-D	b	804,816, 785,794	+	Diffuse partial shell on infrared peaks in Bar.
135		fb	817	+	IR source 817 at N-side; S-filaments follow edge of IR.
136	N 37	fb	823	+	
137		b		0	Arc and sharp filaments in infrared emission.
137a		vb	851	+	Knot in DEM 137 on infrared emission peak 851.
138	N 38	b	831	+	Knot on SE-side of nebula. Nebula 3'N of IR source 831.
139		vf		0	Diffuse nebula follows infrared edge.
140		fb	841	0	Near SAO 249253 (Id 814; see Table 5.A). Shell-like filaments in infrared complex 880 (DEM 152).

Table 7, continued (4).

(1)	(2)	(3)	(4)	(5)	(6)
DEM Id	Henize Id	Intensity of H- $\alpha$	Infrared Id	Detection quality	Remarks
141	N 41	b		0	On extension in infrared complex 880 (DEM 152).
142		b	878	+	Shell with sharp filaments on infrared emission peak.
143		f	847	+	Two knots (clusters?) 3'S of infrared source 847.
144		f		0	On extension in infrared complex 880 (DEM 152).
145	N127B	b	872	+	Knot in Bar; close to DEM 149; 2'M of IR source 872.
146	N197	vb	864	+	
147		f	866	0	In Bar; 4'N of 866.
148		f	866	0	In Bar; 4'E of infrared source 866.
149	N127A	b	872	+	Knot in Bar; in between DEM 145 and 153.
150	N 44J	vb	855	+	Knot.
151		fb	839	0	Filamentary loop in infrared complex 880 (DEM 152).
151a	N 44F	vb	861	+	
152	N 44B,C	vb	876,880,		
			887	+	Elliptical ring at centre of infrared complex 880.
153		fb	872	+	Knot close to DEM 149; in Bar 2'E of 872.
154		fb	830,846,		
			852	0	Arc and filaments resemble infrared emission.
155	N 43	fb	932	+	Filaments corresponds to IR source 932, surrounding 895.
155a		b	895	+	Diffuse circular region corresponds to IR source 895.
156	N 44I	vb	894	0	Knot 3'N of 894; close to infrared complex 880, DEM 152).
157	N128	f	891	0	Diffuse nebula on infrared extension in extended emission.
158	N 44G,K	b	888	0	Close to IR complex 880 (DEM 152); source 888 in between two knots.
159		fb		0	Diffuse shell on IR complex 880 (DEM 152).
160	N 44D,H	vb	911,925	+	Several dense nuclei near infrared complex 880 (DEM 152).
161	N 45	fb	900	+	On infrared peak 900.
162	N 46	b	919	+	Knot.
163	N130	b	916	+	Knot.
164	N200	fb	858,924,		
			960	0	Shell on infrared extended emission.
165	N198	b	910,929,		
			966,985,		
			988	+	Filament around infrared sources 929 and 910.
166a	N 44L	b	925	+	Knot; DEM 166 cannot be separated; close to DEM 160.
166b	N 44E	b	925	+	Knot; DEM 166 cannot be separated; close to DEM 160.
167	N 44N	b	938,946	+	Irregular filamentary shell and knot on IR complex 880 (DEM 152).
168	N131	fb	921	0	Knot in Bar; 2'N of infrared source 921.
169	N 44M	b	943	+	Knot near infrared complex 880 (DEM 152).
170		f	948	+	4'SE of IR source 948; near IR complex 880 (DEM 152).
171	N132J,G	b		0	In Bar; on infrared gradient to 955.
172	N132A	fb	941	+	Diffuse arc in Bar.
173	N132B,C,E,I	fb	955	+	Four knots in Bar on IR peak 955; knots cannot be separated.
174	N138D,B	b	961	+	Diffuse shell.
175		fb	952	+	On infrared gradient to complex 1015 (DEM 189).
175a	N 48E	fb	983	+	Infrared source on S-part of elliptical shell.
176a	N137A	b		0	Knot on infrared extension related to DEM 177.
176b	N137	fb		0	Knot on infrared extension related to DEM 177.
177	N140	fb (see Remarks)		+	Extended filaments follow IR emission; related IR sources: 927,944,947,958,965,968,975,984,987,1005.
178		fb	977	+	2'S of infrared source 977.
179	N136C	b	978	+	Knot.
180	N136A	vb	999	+	Knot and arc.

Table 7, continued (5).

321		f	1733	+	On infrared source 1733. DEM 318-321 are not separable.
322	N180C	vb	1740	+	Diffuse nebula near infrared complex 1744 (DEM 323).
323	N180A,B	vb	1743,1744	+	Circular filaments; infrared complex 1744.
324		f		-	Diffuse nebula on edge on infrared extended emission.
325		b		0	Diffuse shell N of DEM 323, on infrared gradient to 1744.
326	N180	fb	1741,1749	+	Shell surrounds DEM 323 and follows infrared outline around infrared complex 1744.
327		vf	1747	+	Diffuse nebula on edge of infrared extended emission.
328		vf	1753,1778	+	IR follows arc nebula. At E-end of arc: 1791 also in nebula.
329		f	1767	+	Galaxy?

Note to Table 7:

a) See Section 5.2 in the text.

#### 5.1.4. Stars: Conclusion

Emission from stellar photospheres has been detected by us from foreground SAO stars. Some stars in the LMC have been detected which have infrared excesses due to dust shells. Probably no photospheric infrared emission from LMC-stars has been detected.

#### 5.2. H $\alpha$ nebulosities in the LMC

A good overall agreement between H $\alpha$  emission regions and IRAS emission was already noted by Schwering (1985). In Table 7 we present a more detailed comparison of the IRAS data with the H $\alpha$  catalogues of Henize (1956) and of Davies *et al.* (1976, henceforth DEM). The DEM catalogues contains 329 entries ranging in size from 0' to 60'. All DEM entries are covered by the IRAS DPM maps. About 75 % of all the bright H $\alpha$  nebulosities (very bright, bright or fairly bright) have clear infrared counterparts (good

quality detections), 20 % have possible counterparts (medium quality) and the remaining 5 % do not show clear infrared emission (poor quality). For the fainter nebulosities (faint or very faint) the statistics are 50 % detected in the infrared, and 30 % possible detections, while the remaining 20 % does not show clear infrared emission. We conclude that there is a higher detection probability in the infrared for the brighter HII regions. We detected infrared emission from about 75 % of the compact  $H\alpha$  knots, while 60 % of the shells were detected. These statistics are very similar to the SMC  $H\alpha$ -statistics (see Chapter II).

The whole face of the LMC is covered by  $H\alpha$  nebulosities (see DEM, 1976), and also by 60 and 100  $\mu\text{m}$  infrared radiation. From this comparison, we see that the discrete infrared sources correlate well with HII regions, and that HII regions are one of the main contributors to the infrared radiation in the LMC.

In the SMC we detected infrared emission from the supergiant shell SGS 1 (Meaburn, 1980; see Appendix A in Chapter II). On the infrared maps of the LMC there is evidence for infrared supergiant shells following the supergiant  $H\alpha$  shells of Meaburn. Shell SGS 1 (North of N 11) is visible at the edge of the maps, especially at 60 and 100  $\mu\text{m}$  (see also Appendix A). Also clear infrared emission is found from SGS 4 and 5 (Appendix A). These three supergiant shells are relatively isolated from the bulk of the infrared extended emission of the LMC. Shell numbers 2 and 3 (surrounding 30 Doradus) are more complicated to be found, but there is evidence for infrared emission following their edges. Shells 6, 7, 8 and 9 are incomplete in  $H\alpha$ , but comparison with the infrared maps shows some evidence for counterparts. However, the complicated structure of the LMC's infrared emission could well give rise to spurious identifications of such incomplete structure. We conclude that shells 1, 2, 4 and 5 are clearly present in the infrared and that there is some evidence for possible infrared emission from the shells 3, 6, 7, 8 and 9.

### 5.3. Globular clusters in the LMC

We compared the list of globular clusters given by van den Bergh (1981) with our source list and the infrared maps. This is a limited set of the 1603 clusters from Shapley and Lindsay (1963), Lyngå and Westerlund (1963) and Hodge and Sexton (1966). The positional uncertainty of most of these clusters is more than  $1'$ . Many of the clusters listed in these three catalogues are open clusters, embedded in HII regions. We searched deeper on the maps than in Table 3. In total we detected infrared emission from the direction of 41 clusters, of which 33 have associations in Table 3. Twenty-two of these infrared sources also are present in Table 7, indicating the confusion with HII regions. Of these 41 possible detections three have good detection qualities, showing emission at 12 and possibly 25  $\mu\text{m}$ . These clusters are NGC 1978, 2002, 2100. NGC 1978 and 2100 are blue globular clusters (Hodge, 1984). Eleven clusters have medium detection quality, of which two belong to the brighter ones: NGC 1818 and 2004. Results of this comparison are given in Table 8.

### 5.4. Supernova remnants in the LMC

We checked the list of 25 supernova remnants of Mathewson *et al.* (1983; their Table 1). All SNRs are smaller ( $0.1 < \text{size} < 5'$ ) than the IRAS beam size at 100  $\mu\text{m}$ . Table 9 summarizes the results. Five SNRs show good quality infrared emission: these are 0505–67.9, 0509–68.7, 0525–66.1, 0535–66.0 and 0538–69.1. There are eight SNRs which show

Table 8. Clusters in the LMC (Shapley and Lindsay, 1963; Lyngå and Westerlund, 1963; Hodge and Sexton, 1966) with infrared counterparts.

## Notes to Table 8:

a) Only clusters which have possible infrared counterparts are given.

These are taken from the selection of globular clusters of van den Bergh (1981).

b) Twenty infrared associations which were already referred to in Table 7 (HII regions) have been denoted in column 9, together with their HII region number. One association is probably a SAO star. Associations 522, 1126 and 1582 have S-type infrared spectra; all other associations have C- or M-type spectra.

c) See Section 5.3 in the text.

possible infrared emission (medium quality). Note that all five detected remnants have sizes less than about 1'; but not all the ten small (< 100" diameter) SNRs were detected. Two of the detected ones (N 49 and N 63A) correspond to the SNRs recently found by Graham *et al.* (1987). Their two other detections are too confused to be identified unambiguously.

Notes to Table 9.

- a) All associations with Table 3 within 5' are given as remarks, but only the closest one is given in column 2. Thirteen listed associations were already referred to in Table 7 (N11 regions; see column 5). All associations, except 1522, have C- or W-type infrared spectra.
- b) See Section 5.4 in the text.

### 5.5. Planetary nebulae in the LMC

We compared the DPM infrared maps and the source list with the planetary nebulae identified by Sanduleak *et al.* (1978) and Sanduleak (1984). Of their list of 128 nebulae numbers Sk 2, 3, 79, 81, 97 - 104A are not covered by the IRAS DPM observations. The sizes of these nebulae are of order 1". Thirteen nebulae (Sk 1, 11, 28, 29, 31, 36, 51, 58, 62, 64, 75, 78, 85) have probably infrared counterparts, and we have possible detections of seventeen. We give results of the comparison in Table 10. Again we searched deeper than in Table 3. Thirty-two nebulae have close infrared associations in Table 3.

The contribution of line emission from planetary nebulae to the infrared emission in the IRAS bands can be very high (see Pottasch, 1986). Nebula Sk 64 is associated to a

Table 10. Planetary nebulae in the LMC (Sanduleak et al., 1978; Sanduleak, 1984).

very bright infrared object (LI-LMC 1100). Its flux density ratio  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  and  $f_{25\mu\text{m}}/f_{60\mu\text{m}}$  gives  $T_c \approx 140$  K (using a  $\lambda^{-1}$  emissivity). The 60/100  $\mu\text{m}$  ratio suggests  $T_c \approx 95$  K; probably the 100  $\mu\text{m}$  emission is partly due to more extended emission, hence lowering the temperature. Assuming that we are dealing with continuum emission only we can estimate the total amount of infrared radiation coming from this 140 K nebulae by extrapolating the spectrum over the whole infrared wavelength range (1 – 500  $\mu\text{m}$ ), this gives  $L_{\text{IR}} \approx 9.3 \times 10^5 L_{\odot}$ . For the brightest Galactic planetary nebula NGC 7027 (not observed by IRAS) Gathier (1984) adopts  $L_{\text{IR}} \approx 1.6 \times 10^4 L_{\odot}$  (60 times lower). Another Galactic planetary nebula NGC 6537 the IRAS PSC gives flux densities of 7.7, 58.3, 190

Notes to Table 11:

- a) The positions of the dark clouds have been taken from Hodge (1972; Table 1).  
b) All associations, except 1142, have H-type or C-type infrared spectra. Eleven infrared associations were previously included in Table 7 of HII regions (see remarks in column 4).  
c) See Section 5.6 in the text.

and 166 Jy at 12, 25, 60 and 100  $\mu\text{m}$ . When we assume a distance of 2.4 kpc for NGC 6537 (Gathier, 1984), a nebula with the same infrared brightness as NGC 6537 would have flux densities of 0.02, 0.12, 0.4 and 0.3 Jy in the IRAS bands at the distance of the LMC. This is about equal to our detection limits. For most identifications other than the brightest (Sk 64) we actually find 25  $\mu\text{m}$  flux densities of this order of magnitude (see Table 10). Sk 64 is about 200 times brighter at 12 and 25  $\mu\text{m}$  and 20 times at 60 and 100  $\mu\text{m}$ . There might be some confusion with NGC 1984 (see Table 8) but the spectrum is too hot for dust associated with an HII region ( $T_c \approx 40$  K). The contribution of line emission coming from this planetary nebula could be very high which could give rise to high estimates of the total infrared emission. Ten of the probable planetary nebulae have their infrared emission peak at 25 or 60  $\mu\text{m}$ , which is typical for planetary nebulae.

### 5.6. Dark clouds in the LMC

We compared the infrared data with the dark nebulae listed by Hodge (1972). Hodge discussed the uncertainties related to incompleteness of his list; see also the review by Israel (1984). These 68 dark clouds range in size from 1' to 21' x 8' and they are mainly positioned in the Bar and the Greater Doradus area. In the comparison we used positions from his Table 1. Results are listed in Table 11. Thirty-five clouds have one or more association in Table 3. Most clouds can be associated with an infrared feature but clouds 7 and 12 are associated with an infrared minimum.

## 6. Conclusions

In the LMC DPM maps, 1823 discrete sources were found; 1011 of these are identified with sources in the IRAS Point Source Catalog (PSC) and forty-nine correspond to sources in the IRAS Small Scale Structure Catalog (SSS). We found a total of 802 sources not listed

in either of these catalogues. In many cases, we determine actual flux densities for sources while the PSC gives only upper limits. Most sources are associated with known HII regions in the LMC. At the positions of known objects in the LMC, we conducted deeper searches of the maps. The results are as follows.

Out of 163 SAO stars, we detected infrared emission from 57, and possibly 43 more. No catalogued Radcliffe-stars in the LMC were identified with certainty, but 253 infrared sources with stellar-type infrared spectra were found. Three LMC globular clusters (NGC 1978, 2002 and 2100) were also detected. From five small size supernova remnants infrared emission was detected. Infrared emission is seen towards thirteen, and possibly seventeen more, planetary nebulae (out of 128). Of these nebulae, Sk 64 shows very strong infrared emission (about 100 times brighter than the brightest known Galactic planetary nebula).

### **Acknowledgements**

I wish to thank the following people: The SDAS team that supported the first reduction stage and assisted PS during his stay at JPL; E. Kopan, P. Alphenaar, A. Vos and D. Hogeweg for writing the necessary software; Drs. H. Habing, J. Emerson and T. de Jong for scheduling the observations; Drs. H. Habing, F. Israel, W. Rice, R. Walterbos and H. Caspers for discussions. I want to thank Mrs. H. Vesteege-Hensel for typing various tables and source lists. I am grateful for financial support from the Space Research Organisation in the Netherlands (SRON), a subsidiary of the Netherlands Organization for Scientific Research (NWO) during my stay at JPL. I also want to thank the Astronomical Data Center at the NASA Goddard Space Flight Center for providing the SAO Catalog (version 1984).

## Appendix A: Additions to the Infrared Source List

### A.1. Introduction

This infrared survey at 12, 25, 60 and 100  $\mu\text{m}$  covers the entire LMC. Galactic foreground emission is coming in at the East and South edges of the LMC (see Fig. 1 in Chapter II). At the North and West edges however the DPM derived maps do not have much overlap with empty regions, and some prominent  $\text{H}\alpha$  features (Supergiant shells 1 and 5; Meaburn, 1980) are not entirely covered by the DPM maps. To complement the maps obtained from the Additional Observations, we derived IRAS maps using Survey data to cover these regions. Because these maps are produced from a different database than the DPM derived maps described in this chapter, we decided to add the analysis of these maps in an Appendix.

### A.2. Observations and data reduction

The maps used in this Appendix are based on Co-added IRAS Survey data, produced at Leiden Observatory. We did not use the IRAS 16 $\times$ 5 Skyflux images (IRAS, 1985a) because of their lower resolution (4' – 6'). The Co-added Survey data give a resolution that is equal to the resolution of the Additional Observations (see Section 3). A description of the method of Co-adding is given in Chapter II.

We chose seven connecting fields starting at the North-East corner of the LMC following the North edge to the North-West corner, and downwards following the West edge to the South-West corner of the LMC. The IRAS Survey scans that were found covering these regions; there are between 40 and 100 scans in each field (some scans were left out in order to select a certain scan angle). The LMC is positioned at the Ecliptic Pole and hence the Zodiacal emission does not vary (see Skyflux's HCON-1, HCON-2 and HCON-3), allowing us to add all data from the three HCONs. We allowed for overlap between the DPM and Co-added maps. The IRAS Survey scans were gridded onto 2 $\times$ 11 x 2 $\times$ 11 maps. As the low level infrared contours from the Co-added and the neighbouring DPM maps connect reasonably well, we did not attempt to further improve on the background correction.

### A.3. The maps of infrared radiation

The maps of these seven fields are shown by Schwering and Israel (1988b). The outer edges of these fields show some increased noise and non-covered areas of  $\sim 10'$ . Other characteristics of the Co-added maps are given in Table A.1.

Comparing Table A.1 with Table 2 we note that the noise is about 2.5 times less at 12 and 25  $\mu\text{m}$  and 5 – 8 times less at 60 and 100  $\mu\text{m}$  compared to the AOs. This can be explained by the lower amount of extended emission in the maps (especially at 60 and 100  $\mu\text{m}$ ). The zero-level is more uncertain (about 5 times) at 12 and 25  $\mu\text{m}$ , because no extra zero-level correction has been done on the maps; and similar at 60 and 100  $\mu\text{m}$ . The stripe residuals are somewhat less ( $\sim 3$  – 10 times).

**Table A.1.** *Description of the LMC Co-added map characteristics.*

Characteristic (Unit) <sup>a)</sup>	Wavelength band			
	12 $\mu\text{m}$	25 $\mu\text{m}$	60 $\mu\text{m}$	100 $\mu\text{m}$
Median noise (MJy/sr) <sup>b)</sup>	0.040	0.037	0.035	0.07
( $10^{-8}$ Watt m <sup>-2</sup> sr <sup>-1</sup> )	0.54	0.19	0.091	0.07
Zero-level uncertainty (MJy/sr)	0.096	0.19	0.30	1.0
( $10^{-8}$ Watt m <sup>-2</sup> sr <sup>-1</sup> )	1.3	1.0	0.78	1.0
Stripe residuals (MJy/sr) <sup>c)</sup>	0.045	0.12	0.078	0.2
( $10^{-8}$ Watt m <sup>-2</sup> sr <sup>-1</sup> )	0.6	0.6	0.2	0.2
Sensitivity (MJy/sr) <sup>d)</sup>	0.3	0.3	0.4	0.6
( $10^{-8}$ Watt m <sup>-2</sup> sr <sup>-1</sup> )	4	2	1	0.5

Notes to Table A.1:

- a) Average values for the seven edge fields are given (30 % spread).
- b) The value of the median noise is influenced somewhat by the extended emission of the LMC itself, but not so much as in Table 2. An improvement of a factor of 2 – 3 relative to the individual detector scans has been realized.
- c) Higher stripe levels than the average level given in the table can occur.
- d) The sensitivity indicates the intensity limits of Table A.2.

In some Co-added maps we used a wide range of scan angles. The advantage is that we have more scans which reduces the noise level somewhat, and the point spread function (at 12 and 25  $\mu\text{m}$ ) has a particular shape which enables easier detection of point sources. The disadvantage of it is that the photometric accuracy drops due to the complicated point source shape (especially for extended emission at 12 and 25  $\mu\text{m}$ ). Three fields do not show this effect because the scan angles were carefully chosen to be roughly identical.

The maps presented in this Appendix give better information about the connection of the LMC with the infrared background in the emptier North and West regions.

#### A.4. Additions to the Infrared Source List in the LMC

We have searched these maps in the same way as we searched the DPM maps in Section 4. Note that we have only a single map of these fields in contrast to the two (orthogonally scanned) DPM-maps. Table A.2 contains the additions to the source list of Table 3.

We checked all sources from the edge of the DPM-maps (Table 3) and all sources from the IRAS PSC (IRAS, 1985a) and the IRAS SSS (IRAS 1985b). The IRAS PSC and

SSS are based on the same data that were used in preparing the Co-added maps in this Appendix. Most IRAS PSC entries in these seven fields were confirmed by us, and are included in our source list. Only IRAS 05309-6437 is not covered by the Co-added map; and IRAS 05114-6537 (a  $25\ \mu\text{m}$  only source) has not been detected. No IRAS SSS entries are in the newly covered areas. In total we found sixty-eight additional infrared sources in these seven fields of which fifty-two are related to the IRAS PSC catalogue. Thus sixteen new infrared sources were found, and the total number of infrared sources becomes 1891. Some DPM sources at the edge of those maps have been reconfirmed but adjusted in flux densities.

### A.5. Identification of Sources

In this Appendix we are primarily concerned with the identification of all sources that were not already present in the DPM-files (i.e. the area in Co-added fields with  $\alpha_{1950} < 04^{\text{h}}46^{\text{m}}$  or  $\delta_{1950} > -65^{\circ}20'$ ). For the identification of known objects we searched deeper than the infrared source list. None of the Radcliffe LMC-stars (Feast *et al.*, 1960), known supernova remnants (Mathewson *et al.*, 1983) nor any of the known dark clouds (Hodge, 1974) in the LMC are present in these areas.

#### A.5.1. Stars in the Co-added fields

In Table A.3 we list forty foreground stars from the SAO Catalog (1966) that are present in these areas in the seven Co-added fields and their colour-corrected 12 and  $25\ \mu\text{m}$  flux densities. Twelve of them show good quality  $12\ \mu\text{m}$  emission and five show medium quality emission.

Infrared LI-LMC 1842 corresponds to the non-LMC variable star RT Men (see Kukarkin *et al.*, 1969, 1970, 1971).

#### A.5.2. $\text{H}\alpha$ nebulosities in the LMC

The  $\text{H}\alpha$  nebulosities of DEM (1976) and their related infrared emission are described in Section 5.2. The maps in this Appendix show additional information on the supergiant shells 1, 4 and 5 (Meaburn, 1980) at the Northern edge of the LMC.

#### A.5.3. Globular clusters in the LMC

The area of interest to this Appendix contains four clusters from the list of van den Bergh (1981): NGC 1644, 1651, 1652 and NGC 1831. Only NGC 1651 shows some possible 60 and  $100\ \mu\text{m}$  infrared emission and is positioned at  $2'1$  NE of infrared source LI-LMC 1846.

#### A.5.4. Planetary nebulae in the LMC

The Co-added fields contain four planetary nebulae of the list of Sanduleak *et al.* (1978) and Sanduleak (1984): Sk 1, 2, 3 and 4. Additional data confirm the detection of Sk 1 (see Section 5.5; Table 10). Sk 2, 3 and 4 have not been detected on the Co-added infrared maps.

Notes to Table A.3:

a) The 12 and 25  $\mu$ m flux densities in this table are colour-corrected (see Table 5.A).b) Detection qualities at 12  $\mu$ m are good (+), medium (0) or poor (-).

c) See Section A.5.1 in Appendix A.

## A.6. Conclusions

Infrared emission in IRAS Co-added maps at 12, 25, 60 and 100  $\mu$ m at the North and West edges of the Large Magellanic Cloud are analysed; the maps show supergiant shells 1, 4 and 5. In those maps we found 68 infrared sources, which brings the total of infrared sources in and around the LMC to 1891. In the areas that were searched all but one IRAS Point Sources (PSC) were detected; no IRAS Small Scale Structure (SSS) catalogue entries are available in these fields. Sixteen infrared sources are new detections. We identified the

infrared sources where possible. Seventeen foreground SAO stars were detected in these fields, one variable star RT Men and possibly one globular cluster.

## Chapter IV

### GALACTIC INFRARED FOREGROUND EMISSION IN THE DIRECTION OF THE MAGELLANIC CLOUDS

#### 1. Introduction

For a reliable interpretation of measurements in the Magellanic Clouds, a good knowledge of the foreground material in our Galaxy (disk and halo) is essential in infrared, visual and ultraviolet wavelength regions. Until now, the line-of-sight towards the Magellanic Clouds has been assumed to contain Galactic gas and dust, mostly situated close to the Sun, with a uniform distribution over the face of the Clouds.

De Vaucouleurs (1955) has presented deep visual photographs of the Clouds on which a spur like feature is shown, that he suggests to be an optical tidal-spiral arm of the LMC. HI radio data (Cleary *et al.*, 1979; Colomb *et al.*, 1980) confirmed this narrow-arc feature, but showed it to have local velocities (+13 km/s) and thus to be foreground. Some years later, the Infrared Astronomical Satellite IRAS (Israel and Schwering, 1986; McGee *et al.*, 1986) also detected this feature in the infrared bands at 60 and 100  $\mu\text{m}$ . Other infrared features related to foreground emission are a bridge (−4 to +8 km/s) between the LMC and Galactic cirrus emission (−20 to +4 km/s) and a thin filament (−4 to +8 km/s). Neither of these features are related to the LMC, and they show that the Galactic foreground is complex and non-uniform. This complexity was also shown by Johnson *et al.* (1982) who used high contrast prints to detect a region of faint filamentary H $\alpha$  nebulosity in the Galactic foreground. Deep visual images of these filaments were presented recently by West *et al.* (1987). While the SMC is largely free from a complex foreground, it is clear that the LMC's foreground infrared emission and dust obscuration vary over much smaller scales than the size of the Cloud itself.

The mean Galactic foreground reddening in the directions of the LMC and SMC has been studied by McNamara and Feltz (1980; and references therein). Although  $E_{B-V}$  is small, there are large discrepancies between the various values derived (LMC: 0.04 – 0.08; SMC: 0.01 – 0.07 magnitude, based on stellar photometry or on the strength of the 2200 Å feature). McNamara and Feltz derive average  $E_{B-V}$  values of  $0.034 \pm 0.004$  and  $0.019 \pm 0.004$  mag for the LMC and SMC foreground respectively, assuming a constant value over the face of each Cloud. An areal search undertaken by them suggests that the foreground colour excess in the SW quadrant of the LMC is about 0.01 mag higher than in the NE quadrant. From the first available IRAS data on the Clouds Israel and Schwering (1986) concluded that the foreground extinction  $E_{B-V}$  towards the LMC varies between 0 and 0.15 mag but on the other hand the extinction towards the SMC is constant at about 0.02 mag. Note that the peak extinction value inside the LMC itself (at 30 Doradus) is about 0.4 mag (Isserstedt, 1975; Israel and Schwering, 1986) and the average Clouds' extinctions are about the same as that of the local Galactic foreground (Koornneef, 1984).

In this chapter we discuss the Clouds' infrared foreground and its relation to atomic hydrogen (HI). First we discuss the infrared and atomic hydrogen data in Section 2. Section

3 contains a derivation and discussion of the foreground infrared stellar contribution. The large scale foreground infrared cirrus component is derived in Section 4, which has been used to correct infrared maps of the Clouds. Thereafter we discuss the infrared-to-HI relation and compare it with those derived by other authors (Section 5). In Section 6 we derive an estimate for the distribution of the Galactic foreground colour excess in the direction of the Magellanic Clouds as well as the relation between infrared intensity and visual extinction, followed by its implications to visual and ultraviolet studies of the Clouds in Section 7. We summarize the conclusions in Section 8.

## 2. Data presentations and handling

### 2.1. Infrared data

Foreground features that we are interested in, extend over an area of  $40^\circ$ . In principle all IRAS large scale structure maps are useful in this study; these are the  $16^\circ 5$  extended emission Skyflux images (IRAS, 1985), Spline-I (van Albada *et al.*, 1985) and the Zodiacal Observations History File data (ZOHF; see IRAS, 1985). The Skyflux maps have some disadvantages; they are relatively small and the LMC is located on four different plates that cannot be connected at 12 and  $25\ \mu\text{m}$  without elaborate (and not yet routine) procedures. Braun, Walker and Deul (priv. comm.) have combined the  $6^\circ \times 6^\circ$  Spline-I maps into  $50^\circ \times 50^\circ$  maps in Galactic coordinates (see *e.g.* Fig. 1 in Chapter II), but because Spline processing was done only for the IRAS 60 and  $100\ \mu\text{m}$  wavelength bands, we preferred to use the ZOHF data, which has all four IRAS bands at 12, 25, 60 and  $100\ \mu\text{m}$ .

Using the ZOHF data has several advantages. For his own use, Deul (1988) has combined the ZOHF scan-data into intensity maps in Galactic coordinates and subtracted his model of the Zodiacal Light (Deul and Wolstencroft, 1988). The residuals of Zodiacal emission in these maps, which are centered near the South Ecliptic Pole (at  $l = 276^\circ$ ,  $b = -30^\circ$ ), are small and negligible compared to residual stripes which are of the order of 0.5, 0.5, 0.2 and  $0.1\ \text{MJy/sr}$  at 12, 25, 60 and  $100\ \mu\text{m}$  respectively. These stripes are definitely of instrumental origin. The resolution of the original ZOHF maps is  $30'$ , which we have convolved to  $48'$  (the HI resolution; see Section 2.2). This angular resolution corresponds to a linear resolution of  $< 1.4\ \text{pc}$  for (local) distances ( $< 100\ \text{pc}$ ) and  $770\ \text{pc}$  at  $55\ \text{kpc}$  (the distance of the Clouds). The final maps, which are presented in Fig. 1, cover the area of  $250^\circ < l < 330^\circ$  and  $-60^\circ < b < 0^\circ$  with  $15'$  pixel size. Note the radial striping pattern centered on the South Ecliptic Pole due to the scan direction of the IRAS satellite, and the Galactic plane at the top of the images. The features discussed in the Introduction are detected at 60 and  $100\ \mu\text{m}$ . The two filaments emerge from the lower left corner of the LMC ( $285^\circ$ ,  $-35^\circ$ ) in the  $(l, b)$  map, one extending downwards to the right and the other straight to the left. The bridge connecting the LMC with Galactic cirrus emission is located at ( $280^\circ$ ,  $-30^\circ$ ). These three features are below the striping level in the 12 and  $25\ \mu\text{m}$  bands; the grey scales are chosen to enhance the low intensity levels and show one of the filaments (going southwards). In all infrared maps presented in this chapter, the surface brightness is derived by deconvolving for the smearing by the IRAS frequency filters under the assumption of an intrinsic source spectrum  $f_\nu \propto \nu^{-1}$ .

Fig. 1.1. IRAS 12 $\mu$ m ZOHF infrared mapFig. 1.3. IRAS 60 $\mu$ m ZOHF infrared mapFig. 1.2. IRAS 25 $\mu$ m ZOHF infrared mapFig. 1.4. IRAS 100 $\mu$ m ZOHF infrared map

**Figure 1.** Zody History File infrared maps at 12, 25, 60 and 100  $\mu$ m with a resolution of 48'. The maps in this chapter are presented in Galactic 1950 coordinates. Note the LMC ( $280^\circ$ ,  $-33^\circ$ ) just right of the middle and the SMC ( $303^\circ$ ,  $-44^\circ$ ) at the lower left of the centre. Darker grey scales indicate higher intensities; they are chosen to enhance low level emission, ranging from 0 – 50 MJy/sr. Contours are at 2, 5, 10, 20, 50, 100, 200, 500, 1000 MJy/sr, similar in all four bands.

## 2.2 Atomic hydrogen data

With the 18-m Parkes radiotelescope (CSIRO) Cleary *et al.* (1979) have observed HI from the Southern Hemisphere for  $\delta < -30^\circ$  (the area with  $|b| < 10^\circ$  was excluded), with a beam size of  $48'$  (HPBW) and velocity sampling of 7 km/s. Drift scans were taken at constant declination, with  $1^\circ$  intervals in declination for  $b \geq -25^\circ$  (velocity range of  $-148 < V_{LSR} < +300$  km/s) and  $2^\circ$  for  $b < -25^\circ$  ( $-230 < V_{LSR} < +218$  km/s) and one beam width intervals in right ascension. Note that there is spatial undersampling and the individual profiles include contributions of both Clouds.

In order to resample the data to  $15'$  pixels we have interpolated the original data by a Lagrangian interpolation of  $4 \times 4$  surrounding pixels. We have integrated the profiles over the velocity range from  $-38$  to  $+38$  km/s. This range was chosen since the local foreground HI, in the direction of the Magellanic Clouds, has velocities ranging from about  $-30$  to  $+20$  km/s (see Colomb *et al.*, 1980). Furthermore we did not want to use a larger range than necessary as this will mean adding up uncorrelated signals, resulting in a higher noise level, and because the Magellanic Clouds start to contribute at  $V_{LSR}$  of about  $+88$  km/s (SMC; McGee and Newton, 1981) and  $+190$  km/s (LMC; Rohlfs *et al.*, 1984). We have derived atomic hydrogen column densities from

$$N_{HI} (10^{20} \text{ H-atoms cm}^{-2}) = 0.0182/\eta_{mb} \int_{-\infty}^{+\infty} (T_A/K) (dv/\text{km s}^{-1})$$

$$\approx 0.0182/\eta_{mb} (\Delta v/\text{km s}^{-1}) \sum_{v=-38\text{km/s}}^{+38\text{km/s}} (T_A/K) \quad (1)$$

with antenna temperatures  $T_A(K)$  and a main beam efficiency  $\eta_{mb} = 0.85$  for the Parkes 18-m telescope. We have implicitly assumed that the HI emission is optically thin. Optical depths larger than 1 occur at low (absolute) latitudes only (Strong *et al.*, 1982; in the Magellanic Cloud foreground region no evidence for this effect was found by McGee *et al.*, 1986). We have compared the final HI map with the qualitative map published by Colomb *et al.* (1980). These maps, which have the same velocity coverage and are constructed from the same data, agree well. We also compared this map with a map containing all available velocities (Deul, 1988) in the area surrounding the Clouds. This shows that our HI map contains 85 – 90 % of the total summed-velocity HI emission. Therefore we may expect an error of at most 15 % from underestimating the velocity range (note that uncorrelated signals might be added in the summed-velocity HI). The distribution of HI column densities is presented in Fig. 2.1. At the position of the Magellanic Clouds we see relatively weak HI compared to the HI at lower  $|b|$ .

In Fig. 2.2 we combine the infrared  $100 \mu\text{m}$  map in contours with the HI column density grey scales map. Note the good correlation of infrared emitting dust with the atomic hydrogen gas of the Galactic foreground at these spatial scales, and the varying Galactic HI foreground towards the LMC. The HI towards the LMC 30 Doradus region and the LMC-Bar is about 30 % less than to other regions of the LMC. Just below the centre of the SMC we see a dense blob of HI which originates from HI structures following

the drift scan with velocities of  $-38 < V_{LSR} < -26$  km/s and with  $+38 > V_{LSR} > +26$  km/s, velocities at which we find only noise in the individual scans. These velocities are too low for the SMC to be responsible for this blob. The blob does not appear on the original maps of Cleary *et al.* (1979). We conclude that it is probably the result of noise blow-up in the processing.

Fig. 2.1. HI column density map

Fig. 2.2. 100  $\mu$ m contour overlay on HI greylevel map

**Figure 2.** Integrated 21-cm HI column density map with a resolution of  $48'$ .

Fig. 2.1. HI column density map. Grey scales enhance the low level intensities and range from 0 – 22, while contours are at 2, 4, 8, 12, 16, 20  $\times 10^{20}$  H-atoms  $\text{cm}^{-2}$ .

Fig. 2.2. Relation in overlay form between the infrared 100  $\mu$ m contour map and the HI column density grey scales map. The infrared contours and neutral hydrogen grey scales are identical as in Fig. 1.4 and 2.1. Note the position of the Magellanic Clouds in the HI map.

### 3. The stellar infrared foreground

The Galactic infrared foreground can be separated into two categories: unresolved stellar sources (mainly at 12 and 25  $\mu\text{m}$ ) and a smooth foreground related to infrared cirrus (mainly at 60 and 100  $\mu\text{m}$ ). The latter will be discussed in Section 4; here we discuss the discrete component.

Due to their distance, stellar members of the Magellanic Clouds are only marginally detectable by IRAS (see Chapters II and III). We have therefore assumed that all sources of the Source Lists in Chapters II (LI-SMC) and III (LI-LMC) with a stellar infrared spectral type (i.e. strongest at 12  $\mu\text{m}$ ) are foreground stars. The stellar foreground infrared data are given in Table 1. Note that we do not include stars with "hot dust" in surrounding shells (OH/IR stars), of which only a few might be present in the foreground. From the number of sources with warm-dust spectra in the source lists and their flux densities we expect an error at 25  $\mu\text{m}$  of no more than  $\sim 2$  Jy. Elias *et al.* (1986) have shown that the brightest warm-dust spectra in the point source lists are LMC-members. If any Galactic OH/IR stars were present they would have been much brighter than these LMC-stars.

The spectra of the integrated stellar flux densities approximately follow the Rayleigh-Jeans tail of the blackbody spectrum for the SMC; for the LMC the 25  $\mu\text{m}$  flux density is too high by about 70 % as predicted from the 12  $\mu\text{m}$  flux density (and follows roughly a 700 K blackbody). For 85 of the LMC foreground stars the 25  $\mu\text{m}$  flux density is close to the detection limit; a possible overestimate of these low values may explain 25 % of the total 25  $\mu\text{m}$  stellar foreground flux density. The twenty-five brightest stars with  $f_{25\mu\text{m}} > 0.4$  Jy show an excess of about 28 % above the extrapolated 12  $\mu\text{m}$  emission. For the brightest foreground stars, the IRAS Point Source Catalog (PSC; IRAS, 1985) gives flux densities at 12  $\mu\text{m}$  which are about 1.2 times higher than in our LMC source list. Although the PSC 25  $\mu\text{m}$  flux densities are similar to ours, they are still 30 % higher than predicted from the extrapolated 12  $\mu\text{m}$  PSC flux densities. For both Clouds the average flux density per star ( $f_{25\mu\text{m}}^0$ ) is very similar, but the total number of stars emitting at 25  $\mu\text{m}$  is very different (for the SMC 30 % of the stars detected at 12  $\mu\text{m}$  are detected at 25  $\mu\text{m}$ , for the LMC this is 60 %). This shows that the difference in the number of stars must be the main reason for the larger 25  $\mu\text{m}$  flux density in the LMC. Note that the colour correction that has to be applied cannot give an explanation for the high ratio  $F_{25\mu\text{m}}/F_{12\mu\text{m}}$  as both bands must be corrected by the same amount ( $f_\nu$  decreases by about 1.4 for a 3000 K blackbody).

The 12  $\mu\text{m}$  stellar foreground surface brightness towards the LMC (area  $8^\circ \times 8^\circ$ ) is two times larger than towards the SMC ( $4^\circ \times 4^\circ$ ) and at 25  $\mu\text{m}$  about 4 times larger. For the SAO stars the ratio of the number of stars (186 in Chapter III and 47 in Chapter II) is just that expected for the difference in area only (indicating identical average surface densities of SAO stars). Note that the surface density of stars detected in the infrared for the LMC foreground is 1.5 times higher than for the SMC foreground. This difference might be explained by stochastic differences in the number of stars, but mainly the higher latitude of the LMC ( $b = -33^\circ$ ) compared to the SMC ( $b = -44^\circ$ ) will have influenced the result. The observed number of stars in the different latitude ranges are given by Mihalas and Binney (1981, Fig. 4.1 therein); for A-type stars it shows a ratio of 1.4 between  $30^\circ < |b| < 40^\circ$  and  $40^\circ < |b| < 50^\circ$ , with a decrease for later types. Note that the Galactic foreground extinction towards the LMC is also a factor of 1.5 higher than towards

the SMC ( $\Delta E_{B-V} = 0.02$ ; see Sections 1 and 6). Its low value ( $A_V < 0.5$  mag) implicates that no bright foreground stars will stay undetected.

The discrete foreground sources contain 3 % (LMC) respectively 10 % (SMC) of the total integrated flux densities of the Clouds at  $12\ \mu\text{m}$  (see Chapter V). Due to the difference in spectral shape between the Clouds' cool dust and Galactic foreground stars, this fraction falls to about 1 % at  $25\ \mu\text{m}$  and much less in the other bands. Hence, there is a negligible contribution of foreground stars to the 25, 60 and  $100\ \mu\text{m}$  flux densities of the Clouds, but the  $12\ \mu\text{m}$  emission of the Clouds must be corrected for the stellar foreground, the SMC more than the LMC.

Table 1. *Stellar infrared foreground emission* <sup>a)</sup>.

IRAS infrared band	$N_*$	$F_\nu$ (Jy)	LMC $f_\nu^{\text{max}}$ (Jy)	$f_\nu^b$ (Jy)	$f_\nu^t$ (Jy)	$N_*$	$F_\nu$ (Jy)	SMC $f_\nu^{\text{max}}$ (Jy)	$f_\nu^b$ (Jy)	$f_\nu^t$ (Jy)
$12\ \mu\text{m}$	253	130.	8.2	0.51	0.51	43	17.	2.6	0.40	0.40
$25\ \mu\text{m}$	154	51.	4.6	0.33	0.20	12	3.5	0.8	0.29	0.08
$60\ \mu\text{m}$	4	3.2	1.2:	0.80:	0.01	1	0.4	0.4	0.40	0.01
$100\ \mu\text{m}$	0	—	—	—	—	0	—	—	—	—

Note to Table 1:

- a) For each Cloud, and for each infrared band the first column  $N_*$  gives the total number of stellar objects. The various flux densities are given in columns 2 – 5:  $F_\nu$  is the sum of the flux densities of all stars;  $f_\nu^{\text{max}}$  is the maximum flux density that occurs in the sample of stars;  $f_\nu^b$  is the average flux density normalized to the number of stars in the band;  $f_\nu^t$  is the average flux density normalized to the total number of stars detected in the  $12\ \mu\text{m}$  band. Note that all flux densities assume an intrinsic spectrum  $f_\nu \propto \nu^{-1}$ .

#### 4. The cirrus infrared foreground

We determine the Galactic infrared cirrus foreground towards the Magellanic Clouds as follows. Because the  $100\ \mu\text{m}$  emission is optically thin, we have detected in the infrared all the dust in the line-of-sight, i.e. Galactic foreground dust and dust in the Magellanic Clouds, that can be regarded as main contributors to the emission between 8 and  $120\ \mu\text{m}$  ( $I_\nu = \int_{\text{Gal+Clouds}} M_d \kappa_\nu B_\nu(T_d) dl$ ; note that the maps have already been corrected for the large scale Zodiacal emission). From the neutral hydrogen gas (which is assumed to be optically thin) we have selected only the velocity range in which the Clouds do not contribute, but we included all the Galactic HI ( $N_{\text{HI}} = \int_{\text{Gal}} n_{\text{HI}} dl$ ). We furthermore assume a constant gas-to-dust ratio for the Galactic foreground and find the relation of gas and dust from comparing the HI with the infrared dust emission. The infrared foreground

is then reconstructed by scaling the HI map taking into account the derived line-of-sight dust temperatures.

#### 4.1. Atomic and molecular hydrogen column densities

The observed HI (see Section 2.2) originates from Galactic foreground material only, after applying the velocity cut-off at 38 km/s

$$N_{HI\ obs} = N_{HI\ Gal} \approx N_H\ Gal. \quad (2)$$

Because there is hardly any CO detected at high Galactic latitudes (Dame and Thaddeus, 1987;  $I_{CO} < 5$  K km/s at  $|b| > 5^\circ$  and  $I_{CO} > 50$  K km/s for the Galactic plane) we expect little molecular hydrogen to be present; hence all the hydrogen gas is in atomic form and the approximation of Equation 2 holds. The same low CO emission is found at high latitudes in the third Galactic quadrant (May *et al.*, 1988). Note that some local high latitude molecular clouds are detected, but none are known in this part of the sky. In the absence of  $H_2$  the HI gas-to-dust ratio should be constant over the whole area.

#### 4.2. Infrared emission

First we study the relation of infrared emission with atomic hydrogen. The 12 and 25  $\mu m$  infrared radiation at the latitudes of the Clouds, is possibly caused by very small grains (with radii  $0.3\text{ nm} < a < 10\text{ nm}$ ) heated to high non-equilibrium temperatures ( $300\text{ K} < T_{12-25\mu m} < 1500\text{ K}$ ) by absorption of single high-energy (ultraviolet) photons (Puget *et al.*, 1985; Draine and Anderson, 1985; Cox *et al.*, 1986). The intensity of the 12 and 25  $\mu m$  emission depends on the temperature distribution of these small grains, and this distribution is not necessarily related to the temperature distribution of the larger grains responsible for the 60 and 100  $\mu m$  emission. As there is a close resemblance of the Galactic 12 and 100  $\mu m$  (cirrus) maps, small grains are expected to be well mixed with the larger grains, and with HI. Hence we would expect a strong relation between  $I_{12\mu m}$  and  $N_{HI}$ . However, the  $1^\circ$  pixel-to-pixel scatter diagrams (Fig. 3.1 and 3.2) do not show a strong relation. There is a large scatter which makes the shape of the relation of 12 and 25  $\mu m$  with HI hard to determine. The range in infrared intensities is in these bands an order of magnitude smaller than for the 60 and 100  $\mu m$  bands. Residual scan-strips and Zodiacal emission in the maps, also contribute to the scatter. Correcting these bands for the 12 – 25  $\mu m$  line-of-sight dust temperature (assuming equilibrium) gives only a marginally improved correlation. The cooler dust grains responsible for the 60 and 100  $\mu m$  emission, are expected to be closely related to the HI distribution (Cox *et al.*, 1986) and therefore should show a good correlation. The scale height of HI and infrared are equal in our Galaxy (Burton and Deul, 1987). The 60 and 100  $\mu m$  intensities have a much wider range in values and the map uncertainties are much smaller. We have determined the relations from the  $^{10}\log I_\nu - ^{10}\log N_{HI}$   $1^\circ$  pixel-to-pixel scatter diagrams, which are given in Fig. 3.3 and 3.4.

**Figure 3.** Pixel-to-pixel scatter diagrams of the infrared emission at the four IRAS bands (in MJy/sr) with the HI column density (in  $10^{20}$  H-atoms  $\text{cm}^{-2}$ ; both  $^{10}\log$ ). The solid or dashed lines correspond to the derived relations (see Table 2). Areas of  $16 \times 16$  pixels ( $1^\circ \times 1^\circ$ ) have been averaged before plotting.

Fig. 3.1.  $12 \mu\text{m}$  infrared map - HI column density.

Fig. 3.2.  $25 \mu\text{m}$  infrared map - HI column density.

Fig. 3.3.  $60 \mu\text{m}$  infrared map - HI column density.

Fig. 3.4.  $100 \mu\text{m}$  infrared map - HI column density.

For the relation in Fig. 3.4 we have used all available pixels as the uncertainties in the  $100 \mu\text{m}$  map are much less than in the other bands. Using the same area as before would lead to only the upper part of the diagram ( $I_{100\mu\text{m}} > 1 \text{ MJy/sr}$ ) but would not influence the choice of the infrared-HI correlation.

We have fitted a power-law relation

$$I_{\nu \text{ Gal}} = \alpha_{\nu} N_{HI \text{ Gal}}^{\beta_{\nu}} \quad (3)$$

to the scatter plots; where  $\alpha_{\nu}$  and  $\beta_{\nu}$  are determined from the figure's offset and slope. The empirical values, which have been derived for the HI range of  $(8 - 20) \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ , are summarized in Table 2. The 60 and 100  $\mu\text{m}$  intensities correlate very well with HI and the diagrams indicate the expected non-linear relation between infrared and HI, which can only be understood when the grain temperature and the HI column densities are correlated. In Section 5.2 we will go into detail in the origin of these non-linearities.

**Table 2.** *Parameters describing the relation of infrared and dust with gas in the Galactic foreground for the specified HI ranges <sup>a)</sup>.*

Data	$\alpha_{\nu}$	$\beta_{\nu}$	Comments
$I_{12\mu\text{m}}$	$0.0019^{+0.003}_{-0.001}$	$2.6 \pm 2.0$	From Fig. 3.1.
$I_{25\mu\text{m}}$	$0.0019^{+0.003}_{-0.001}$	$2.6 \pm 2.0$	Set equal to 12 $\mu\text{m}$ relation; Fig. 3.2.
$I_{60\mu\text{m}}$	$0.00069^{+0.0007}_{-0.0004}$	$3.4 \pm 0.5$	From Fig. 3.3; $N_{HI} = 10 - 20$ .
$I_{100\mu\text{m}}$	$0.082^{+0.06}_{-0.04}$	$2.1 \pm 0.2$	From Fig. 3.4; $N_{HI} = 3 - 20$ .

$T_d$ (K)	$22^{+2}_{-2}$	—	From Fig. 4.2.
$\langle N_d/N_{HI} \rangle$	$0.0024^{+0.0009}_{-0.0009}$	—	Linear fit to Fig. 4.4.
$\langle N_{HI}/N_d \rangle$	$420^{+250}_{-120}$	—	Inversion of $\langle N_d/N_{HI} \rangle$ above.

Note to Table 2:

- a) The coefficients  $\alpha_{\nu}$  and  $\beta_{\nu}$  of Equation 3 are given for the relation of infrared intensity to HI column density of Fig. 3. The values for 12 and 25  $\mu\text{m}$  contain large uncertainties due to the large scatter in Fig. 3, while the 60 and 100  $\mu\text{m}$  relations are much more accurate.  $I_{\nu}$  is expressed in MJy/sr and  $N_{HI}$  in  $10^{20}$  H-atoms  $\text{cm}^{-2}$ . The ratio  $I_{60\mu\text{m}}/I_{100\mu\text{m}}$  increases somewhat with increasing 100  $\mu\text{m}$  intensities. Note the rather constant  $T_d$  and that the dust-to-gas (mass) ratio has been fitted in a linear way ( $\beta_{\nu} \equiv 1$ ).

#### 4.3. Dust temperatures

As a result of the small optical depth of infrared radiation, dust column densities can be derived in each line-of-sight (see Appendix). In general two components, dust in the Galaxy and in the Clouds, are responsible for the infrared emission and hence the dust column densities consist of these two components

$$N_{d \text{ obs}} = N_{d \text{ Gal}} + N_{d \text{ Clouds}}. \quad (4)$$

Fig. 4.1 shows the dust temperature map obtained from the 60 and 100  $\mu\text{m}$  infrared maps. We have assumed a  $\lambda^{-n}$  wavelength dependence for the emissivity (with  $n = 1.5$ , see Appendix) and have applied intensity cut-offs at 0.2 MJy/sr to avoid noise blow-up. Due to the strong dependence of the infrared intensity on the temperature of large dust grains ( $I_\nu \propto T_d^{4+n}$ ) a 15 % variation in temperature of 22 to 25 K (typical cirrus dust temperatures) will change the infrared emission by a factor of 2. Note that the lines-of-sight towards the LMC, the SMC and the Galactic plane are warmer than the Galactic Cloud-foreground. In general we see a correlation between infrared emission and dust temperature. The pixel-to-pixel relation of  $T_d$  with  $N_{HI}$  is given in Fig. 4.2. The mean foreground dust temperature is about 21 K around the LMC with a range in values of 17 – 28 K. The local Galactic foreground dust ( $b \lesssim -10^\circ$ ) thus seems to be at a quite uniform temperature with little variation. Although we have applied an intensity cut-off, some low-level infrared emission areas influenced by striping yield unrealistically high temperatures above 30 K (e.g. at latitudes  $b < -40^\circ$ ; the area with  $250^\circ < l < 280^\circ$  and  $-30^\circ < b < -25^\circ$ ). Note that these stripy areas follow the scan-pattern to the Ecliptic Pole. Uncertainties mainly in the 60  $\mu\text{m}$  map give rise to these artificially high dust temperatures, indicating baseline problems at these positions. These two areas have been cut-out in the quantitative analysis (of e.g. Fig. 3).

#### 4.4. Dust column densities

The use of  $I_{100\mu\text{m}}$  as a measure for the dust content of objects is justified only if objects have single dust temperatures throughout. In general this is not the case and variations of  $I_{100\mu\text{m}}$  with  $T_d$  will occur as described in Section 4.3. We calculated dust mass column densities  $M_d$  by correcting the 100  $\mu\text{m}$  infrared map with the line-of-sight dust temperatures  $T_d$  and dividing by the mass absorption coefficient  $\kappa_{100\mu\text{m}}$ . The resulting map is shown in Fig. 4.3. These column densities are expressed in the number of hydrogen atoms that correspond in mass with the calculated dust column (i.e.  $N_d \equiv M_d/m_{HI}$ ). They are relatively high in the Galactic plane, decreasing towards higher (negative) latitudes. In these "temperature corrected infrared maps", the LMC shows up only marginally as its dust is considerably warmer than the dust in the local Galactic foreground and its dust column densities apparently low. Note the reasonably good overall correlation between the 100  $\mu\text{m}$  infrared emission and the dust column densities, which is a consequence of the rather uniform  $T_d$  distribution. The HI also correlates reasonably well with the dust column density map on these large scales. Fig. 4.4 shows the latter relation in a 1° pixel-to-pixel scatter diagram. Some points in this figure have high values for  $N_d$  ( $> 0.04$ ) for relatively low values for  $N_{HI}$  of  $(5 - 11) \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ . These points, positioned at the upper left of the LMC, can be distinguished in Fig. 4.3 and have somewhat lower dust temperatures. These low temperatures are more influenced by noise and other uncertainties in the 60 or 100  $\mu\text{m}$  maps and have more uncertain dust column densities.

#### 4.5. Gas-to-dust ratio

Dust and gas are assumed to be well mixed in galaxies. Their ratio gives us information on the evolution of galaxies; low dust-to-gas ratios occur in relatively unevolved galaxies (like the Magellanic Clouds). From the area that can be considered free of Cloud infrared emission we now obtain the dimensionless mass-relation between temperature

corrected Galactic foreground infrared emission  $N_d$  and atomic hydrogen emission  $N_{HI}$ ,  $< N_{HI}/N_d >$ . From Fig. 4.4 we derive a value  $< N_{HI}/N_d > = 420^{+250}_{-120}$  (see Table 2). According to our definition of  $N_d$  (Section 4.4), this is the gas-to-dust ratio by mass.

This ratio is determined from data with  $N_{HI}$  of  $(3 - 20) \times 10^{20}$  H-atoms  $\text{cm}^{-2}$  and is 2 - 4 times higher than classical values for our Galaxy (100 - 200, Osterbrock, 1973; Hildebrand, 1983; Savage and Mathis, 1979). Using the same method, van Roermund (priv. comm.) derived a gas-to-dust ratio in the Scorpius region (near  $b = 0^\circ$ ) of  $350 \pm 50$ ; within our errorbars. The formal error in the derived value of  $< N_{HI}/N_d >$  results from the scatter in the figure. Hence it is influenced by problems and artefacts in the infrared and HI data (see Section 2). The real uncertainty in  $< N_{HI}/N_d >$  may be larger as potentially large systematic effects are introduced by uncertainties in dust particle properties (Draine and Anderson, 1985; Hildebrand, 1983). The effect is not easy to quantify but especially the absolute value of the mass absorption coefficient  $\kappa_\nu$  is uncertain. According to Hildebrand (1983) this results in uncertainties which might well be a factor of 2.

The simplest explanation for the difference of the observed gas-to-dust ratio with classical values, is to allow for a spatial variation of the gas-to-dust ratio in the Galaxy. For example there are variations in this ratio for different galaxies (see *e.g.* Koornneef, 1984) and local variations in the Galaxy might also be present. In M31, Walterbos and Schwing (1987) have found a decreasing dust-to-gas ratio ( $I_{cool\ dust}/N_{HI}$ ) for increasing radius (from 0 to 15 kpc) and a similar effect is suggested in our Galaxy by Burton and Deul (1987). Possible variations in the dust-to-gas ratio are indicated in Fig. 5, which shows maps of the ratios  $I_{100\mu\text{m}}/N_{HI}$  and  $N_d/N_{HI}$  over the Galactic foreground. From Fig. 5.1 it is clear that there still is a correlation between  $I_{100\mu\text{m}}/N_{HI}$  and  $I_{100\mu\text{m}}$  (Fig. 1.4); in Fig. 5.2 we see that the correlation between  $N_d/N_{HI}$  and  $I_{100\mu\text{m}}$  is less than this.

The general trend of higher dust-to-gas ratios near the Galactic plane may reflect a latitude dependence of this ratio. Dust, HI and CO all have higher densities near the plane and the observed gas-to-dust ratios indicate a possible relation of it with these forms of gases. Possible evolution effects, causing a higher gas-to-dust ratio at high latitudes, are unexpected; at these latitudes dust and gas are expected to be mixed in a similar way as near the Galactic plane (Mihalas and Binney, 1981; Burton and Deul, 1987).

Figure 4. Foreground dust property maps derived from the infrared maps with a resolution of  $48''$ , and their pixel-to-pixel relation with HI. See page 127.

Fig. 4.1. Dust temperature map derived from the 60 and 100  $\mu\text{m}$  maps assuming an emissivity with a  $\lambda^{-1.5}$  wavelength dependence. An intensity cut-off has been applied at 0.2 MJy/sr. Grey scales enhance the low temperatures and range from 10 - 70 K, while contours are at 20, 30, 40, 50, 60, 70 K.

Fig. 4.2. Linear pixel-to-pixel scatter diagram of  $T_d$  (K) versus  $N_{HI}$  ( $10^{20}$  H-atoms  $\text{cm}^{-2}$ ; each point represents the average of 16 pixels, i.e.  $1^\circ \times 1^\circ$ ).

Fig. 4.3. Dust column density map derived from the 100  $\mu\text{m}$  map and the dust temperature map of Fig. 4.1. Grey scales enhance the low dust columns and range from 0.0 - 0.2 while contours are at 0.001, 0.005, 0.01, 0.05,  $0.1 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ .

Fig. 4.4. Linear pixel-to-pixel scatter diagram of  $N_d$  versus  $N_{HI}$  (both in  $10^{20}$  H-atoms  $\text{cm}^{-2}$ ; each point represents the average of 16 pixels, i.e.  $1^\circ \times 1^\circ$ ). The solid line corresponds to the derived relation of Table 2. The errorbars are drawn dashed.

Fig. 4.1. Dust temperature map

Fig. 4.3. Dust column density map

Fig. 4.2. Pixel-to-pixel scatterplot

Fig. 4.4. Pixel-to-pixel scatterplot

We might have underestimated the HI column densities in two ways: HI optical depths of unity or not all HI in the lines-of-sight is observed. The optical depths of HI are not exactly known. If it is optically thick, its column density is underestimated and this can account for the observed increase of  $I_{100\mu\text{m}}/N_{\text{HI}}$ , close to the plane of the Galaxy ( $|b| < 5^\circ$ ). As variations occur even at high absolute latitudes optical depth effects cannot be important for the observed variations in the gas-to-dust ratio. The HI in the lines-of-sight might be underestimated by 15 %, roughly constant over the foreground. However, to correct the high gas-to-dust ratio an overestimate of the atomic hydrogen content is needed. It does therefore not seem possible to find an explanation for the high gas-to-dust ratio from systematic errors in the neutral hydrogen column densities.

The last possibility is an underestimate of the dust column densities. Draine and Lee (1984) have shown that for certain temperature ranges  $< Q(a, T_d) > /a$  may depend on the dust temperature ( $\propto T_d^2$  for  $T_d < 50$  K; the exact relation depends on the type of grains); then  $\kappa_\nu \equiv \frac{4}{3ap_d} < Q_\nu(a, T_d) >$  also depends on  $T_d$ . The derived line-of-sight temperatures are not influenced by this variation of  $\kappa_\nu$ , but the dust column densities are.

Fig. 5.1.  $I_{100\mu\text{m}}/N_{\text{HI}}$  ratio

Fig. 5.2.  $N_d/N_{\text{HI}}$  ratio

**Figure 5.** Distribution of the ratio of infrared and dust with HI.

Fig. 5.1.  $I_{100\mu\text{m}}/N_{\text{HI}}$  with grey scales enhancing the low ratios between 0 – 3, while contours are at 0.5, 1, 2, 5, 10 ( $\text{MJy sr}^{-1} / (10^{20} \text{ H-atoms cm}^{-2})$ ).

Fig. 5.2.  $N_d/N_{\text{HI}}$  with grey scales enhancing the low ratios between 0 – 0.005, while contours are at 0.0025, 0.0075, 0.02.

The effect of applying a correction for this effect is that dust masses of warm areas would decrease compared to masses in cool areas; and hence the dust-to-gas ratio, which is anti-correlated with  $T_d$  (see below), would show stronger gradients than without correction. By changing the absolute value of  $\kappa_\nu$  we are able to explain the difference; an average value of  $14 \text{ cm}^2 \text{ g}^{-1}$  (2.8 times lower than used) would be needed to obtain the classical gas-to-dust ratio from these observations.

The variations cannot be explained by assuming large amounts of cold dust (with  $T_d = 15 \text{ K}$ , see Cox *et al.*, 1986); we need 2.8 times the amount of observed dust mass in order to obtain  $\langle N_{HI}/N_d \rangle = 150$ . This dust radiates six times less in the infrared than 21 K dust and is therefore undetected by IRAS. There is only little CO detected at these high latitudes and therefore it is unlikely to expect large amounts of  $\text{H}_2$  or associated dust. Note that the Galactic scale height of  $\text{H}_2$  is less than that of HI (Burton and Deul, 1987). The distribution of the gas-to-dust ratio is opposite to what we expect when missing cold dust is needed to have a constant gas-to-dust ratio over the Galaxy (Fig. 5.2); to fix the gas-to-dust ratio we would need a  $\text{H}_2$  distribution which is anti-correlated with HI. This is not expected, and is not observed in CO. Hence large amounts of dust associated with  $\text{H}_2$  cannot be of importance for the variation in the gas-to-dust ratio found in this chapter.

The line-of-sight dust temperature can be overestimated if there is a contribution of very small grains to the  $60 \mu\text{m}$  intensity (the contribution of these grains to the  $100 \mu\text{m}$  intensity is negligible). To estimate the effect we now keep the 60 and  $100 \mu\text{m}$  intensities fixed and define  $\langle N_{HI}/N_d \rangle \equiv 150$ . The average dust temperature has to be dropped from 21 to 18 K, and we need 44 % of the original  $I_{60\mu\text{m}}$  to come from these very small grains; this is a high percentage. A theoretical spectrum for the very small grains is derived from Draine and Anderson (1985). We took the difference of the spectra for  $a_{\text{min}} = 3 \text{ \AA}$  (modified grain size distribution) and the MRN-distribution for  $a_{\text{min}} = 30 \text{ \AA}$ ; the Solar Neighbourhood radiation field was assumed in these calculations. The calculated relative very small grains spectrum is 1, 3, 4.5, 0 at 12, 25, 60 and  $100 \mu\text{m}$ . The average observed spectrum for cool dust (with  $T_d < 30 \text{ K}$ ) is 1, 1, 3.6, 20 at 12, 25, 60 and  $100 \mu\text{m}$ . We have fitted the 25  $\mu\text{m}$  point and 42 % of the 60  $\mu\text{m}$  emission might be coming from these very small grains. Hence just that needed for the difference in gas-to-dust ratio with classical observations. This effect can play a role only at low dust temperatures. At high  $T_d$  the warm dust component is dominating the 60  $\mu\text{m}$  emission.

Due to the presence of multiple or continuous dust temperature components in the line-of-sight the dust temperature in each line-of-sight might also be overestimated. From Chapter VI we find that about 30 % in dust mass can be gained by doing a temperature decomposition in each line-of-sight.

In general the ratio  $N_d/N_{HI}$  decreases with increasing  $T_d$ . There is a steep rise near 22 K with a flat part of 0.0025 above 25 K; there is no clear minimum. This is an indication that for high line-of-sight dust temperatures the dust column density is underestimated. For low temperatures the dust-to-gas ratio rises to values larger than the classical Galactic one. Because we expect the small grain contribution to dominate at these lower temperatures this cannot give the explanation for the observed low dust-to-gas ratio; we expect the temperature overestimation to be the dominating factor resulting in an underestimated  $N_d$ .

## Notes to Table 3:

- a) The average internal colour excess for the Magellanic Clouds are  $E_{B-V} = 0.07 \pm 0.04$  mag for the LMC and  $0.03 \pm 0.03$  mag for the SMC (Koornneef, 1984).
- b) The errors indicate the range of variation of the infrared intensity and the atomic hydrogen column density. The infrared foreground intensities, given here, do not contain a contribution

from the Zodiacal emission. They were obtained by examining the areas surrounding the Clouds (figures of Section 2.1) and by HI-predicted foreground emission (Section 4). For the SMC  $I_{12\mu m}$  is relatively high compared to  $I_{25\mu m}$  due to residual scan-stripping.

- c)  $T_d$  has been calculated by fitting  $\nu^{1.5} B_\nu(T_d)$  to the 60 and 100  $\mu m$  data. The temperatures of the LMC line-of-sight dust ranges from 23 – 41 K and in the SMC from 24 – 35 K.
- d) The average infrared foreground flux density was found from summing pixel areas of the LMC and SMC, and by fitting the foreground and also by using the predicted foreground; from  $f_\nu = I_\nu \Omega$ , where  $\Omega$  is the solid angle of the Clouds ( $8^\circ \times 8^\circ$  for the LMC and  $4^\circ \times 4^\circ$  for the SMC).

The M31 cool dust spectrum was used to extrapolate the 100  $\mu m$  point to the 12 and 25  $\mu m$  points. The ratio  $I_{60\mu m}/I_{100\mu m}$  of 0.18 – 0.19 suggests that this is a good value, however the correlation between infrared and HI at 12 and 25  $\mu m$  wavelengths is very poor (the relative cool dust spectrum of M31, Walterbos and Schwering, 1987, is 0.051, 0.045, 0.15, 1.0 at 12, 25, 60 and 100  $\mu m$  respectively). Note that the 12 and 25  $\mu m$  foreground do not correspond well with this cool dust spectrum.

- e) Note that these relations are logarithmic relations as the magnitude is defined via the logarithmic scale.

The variation in dust temperature in the Galactic foreground is not much (20 – 25 K) but is large enough to explain variations of about a factor of 2 in infrared intensity compared to the HI column density. Hence the use of a constant  $N_d/N_{HI}$  gives better results than the use of  $I_{100\mu m}/N_{HI}$  as the variation for areas at  $b = -30^\circ$  compared to areas at  $b = -10^\circ$  is 1 – 2 for the first ratio and 2 – 3 for the latter ratio. It is important to note here that the absolute value of  $\langle N_{HI}/N_d \rangle$  and hence the difference with other literature values is *not* important for the calculation of the foreground infrared emission, predicted from the constant gas-to-dust ratio and neutral hydrogen column density with the derived dust temperatures; likewise it is not important for comparison with extragalactic gas-to-dust ratios calculated in the *same* way.

#### 4.6. Predicted infrared foreground emission

We have constructed a map of the Galactic foreground infrared emission at 60 and 100  $\mu m$  by converting the dust map (the atomic hydrogen map scaled by  $\langle N_d/N_{HI} \rangle$ ) with the Planck function  $B_\nu$  at the derived line-of-sight dust temperatures  $T_d$ . The temperatures have been set equal to 21 K for the dust towards the Clouds and in the regions influenced by bad scans (see above). The value of 21 K gives the best connection with the area for which  $T_d$  could be derived. We have assumed a similar gas-to-dust ratio towards the Clouds as for the global Galactic foreground. Hence the predicted infrared intensity  $I_\nu^{for}$  for the Galactic foreground becomes

$$I_\nu^{for} = (N_{HI} / \langle N_{HI}/N_d \rangle) m_{HI} \kappa_\nu B_\nu(T_d). \quad (5)$$

These foreground infrared maps are presented in Fig. 6.1 and 6.4 in a similar representation as Fig. 1. We see structure in the foreground emission on the same scales as the resolution ( $48''$ ). Using a prediction based on this equation results in a consistent foreground at 60 and  $100\ \mu\text{m}$  for a constant gas-to-dust ratio in the Galaxy. The HI-predicted foreground has been compared with the original infrared maps at 60 and  $100\ \mu\text{m}$ . On average a linear relation, with slope unity, is seen in both bands. However, there is a considerable amount of scatter in the diagrams and some extreme data points are far off. Another way to obtain foreground emission is to use the relation between  $I_{60\mu\text{m}}$  and  $I_{100\mu\text{m}}$  with  $N_{HI}$  directly. In the latter case a variable gas-to-dust ratio has to be allowed. Local differences compared to the globally derived relations, make that the results of both methods are not very different and contain equal uncertainties.

We have subtracted the HI-predicted foreground infrared emission from the observed total infrared maps; these maps are shown in Fig. 6.2 and 6.5. Fig. 6.3 and 6.6 give the ratio of the predicted infrared foreground emission over the total observed infrared radiation at 60 and  $100\ \mu\text{m}$ . From Fig. 6.2 we see that the subtraction works fine at  $60\ \mu\text{m}$ , but it shows a foreground underestimation of  $0.1\ \text{MJy/sr}$  in the area towards the LMC (especially at  $l = 275^\circ$ ,  $b = -40^\circ$ ). This value is four times lower than the error estimate due to the AO-foreground adjustment on the LMC in Chapter III. At  $100\ \mu\text{m}$  the foreground surrounding the LMC is overestimated by roughly  $1\ \text{MJy/sr}$  (similar to Chapter III). The errors in the AO-foreground of the SMC (Chapter II) are much smaller than these values. The SMC DPM-field is much smaller and the SMC-foreground is not very complicated, therefore the infrared foreground can be handled better locally (Chapter II) instead of globally (as in this chapter). Note the differences of Fig. 6 with the original infrared maps of Fig. 1. For the 12 and  $25\ \mu\text{m}$  bands the lack of correlation of the intensity with the neutral hydrogen column density makes this foreground prediction unreliable. From Fig. 1 we see that the foregrounds in these bands are much weaker and less complex than in the 60 and  $100\ \mu\text{m}$  bands.

We have compared the application of the HI-predicted foreground removal with fitting the infrared foreground by a (2-dimensional) plane (see Chapters II and III). This results in small scale differences. The fit shows more foreground in the upper-left corner of Fig. 6 in both infrared bands. At  $60\ \mu\text{m}$  the planar fit underestimates the foreground in the LMC-South (in declination) and overestimates the foreground in the LMC-North. At  $100\ \mu\text{m}$  the foreground towards the whole LMC, except the Bar and the Greater 30 Doradus Region is underestimated; in these two regions the fit overestimates the HI-predicted foreground emission. On average the  $60\ \mu\text{m}$  fit is quite correct and predicts the same foreground (see Table 3). The fitted  $100\ \mu\text{m}$  foreground is (on average) 20 % lower than the HI-predicted foreground.

For the SMC, a comparison with the AO-maps shows that the foreground removal based on  $N_{HI}$ , is not an improvement. On the other hand, the HI-predicted infrared foreground towards the LMC is very realistic and is a good estimate for the true Galactic foreground in that region. It gives a better result in foreground subtraction than by removing a fitted plane. The foreground data is summarized in Table 3. The total foreground flux density at  $60\ \mu\text{m}$  is 10 – 20 % of the integrated Clouds flux density; at  $100\ \mu\text{m}$  it is even 30 – 40 %. The extrapolated values for 12 and  $25\ \mu\text{m}$  are also relatively high (30 – 70 %) but might be overestimated due to the fact that the infrared spectrum is not

as cool as expected (note that these percentages do not include the Zodiacal emission). The higher percentages are for the SMC, which is fourteen times weaker at 60 and 100  $\mu\text{m}$  than the LMC. The SMC foreground intensities reach 0.3 – 0.6 times the intensities of the LMC foreground.

## 5. The relation between Galactic infrared and atomic hydrogen emission

### 5.1. Comparison of Galactic infrared–atomic hydrogen relations

From the available foreground infrared and atomic hydrogen data we have derived the large scale ratio  $I_{100\mu\text{m}}/N_{\text{HI}}$  in Section 4. Global values for this ratio have been derived from Table 3. Although there are reasons (see Section 4) that make  $I_{100\mu\text{m}}/N_{\text{HI}}$  not the ideal ratio to study, several authors have done so and we therefore compare the Magellanic Cloud foreground ratios with the ratios derived by other authors. In Table 4 we have summarized the literature values together with our own ratios.

Table 4. Galactic studies of infrared–to–HI ratios.

Region <sup>a)</sup>	$I_{100\mu\text{m}}/N_{\text{HI}}^{\text{b)}$	$I_{60\mu\text{m}}/I_{100\mu\text{m}}^{\text{b)}$	$N_{\text{HI}}$ range <sup>b)</sup>	Authors
Global studies:

Seven regions	$0.5 - 2.4$	$0.18 - 0.30$	2 – 15	Boulanger and Perault (1988).
Objects average	$1.5 \pm 0.5$	$0.18 - 0.32$	2 – 20	

Notes to Table 4:

a) For a better description of the studied regions we refer to the separate papers.

b)  $I_{100\mu\text{m}}/N_{\text{HI}}$  is given in units of  $(\text{MJy/sr})/(10^{20} \text{ H-atoms cm}^{-2})$ ,  $I_{60\mu\text{m}}/I_{100\mu\text{m}}$  is the ratio of MJy/sr, and the HI range is given in  $10^{20} \text{ H-atoms cm}^{-2}$ .

c) The values of de Vries have been converted to a similar quantity from his relation  $A_B/I_{100\mu\text{m}} = (0.11 \pm 0.01) \text{ mag} / (\text{MJy/sr})$  using  $E_{B-V}/N_{\text{H}}$  of Savage and Mathis (1979).

Two different types of studies need to be separated. First of all there are global studies, using integrated HI and infrared over the full line-of-sight (de Vries, 1986; Terebey and Fich, 1986; McGee *et al.*, 1986; Boulanger and Perault, 1988; this chapter). Second, there are studies of discrete objects, in which case the relative contribution of the object is found by removing the foreground emission (Boulanger *et al.*, 1985; Deul, 1988; Boulanger and Perault, 1988). Table 4 shows good agreement between the listed global values. Note that the SMC foreground value is two times lower than the global average of  $0.6 \pm 0.2$ . The ratios derived for local areas are on average 2.5 times higher. Due to the correspondence of the global infrared-to-HI ratios we find these to be quite accurate. The variation in the ratios for the local estimates is much larger than for the global estimate, due to the larger spread in 60 – 100  $\mu\text{m}$  colour temperatures.

Boulanger and Perault (1988) have shown that the longitude integrated data follows, on large scales, a cosecant-law with Galactic latitude. Using Parkes 64-m telescope HI data McGee *et al.* (1986) found the infrared-to-HI relation to be quite loose on scales of  $15'$ ; their average value of 0.74 corresponds well with our global average. Large scale variations are indicated in Fig. 5.1 where we find ratios of 0.2 – 2.0. These differences make it clear that extrapolations of  $I_{100\mu\text{m}}/N_{\text{HI}}$  to other areas of the sky, as done *e.g.* by Boulanger *et al.* (1985), in general are wrong. If we assume a constant dust-to-gas ratio,  $I_{100\mu\text{m}}/N_{\text{HI}}$  will be constant only if the dust temperature is constant. Hence from Fig. 4.1 we see that this is only the case on small scales ( $< 20^\circ$ ). Over the whole field a wide range of temperatures exist (17 – 28 K) and, due to the strong dependence of infrared intensity on dust temperature the ratio  $I_{100\mu\text{m}}/N_{\text{HI}}$  will vary by about a factor of 4. Extrapolations can be done better with temperature corrected infrared data ("dust column densities").

## 5.2. Variations in the relation between infrared intensity and atomic hydrogen column density

We have found a large scale relation between 100  $\mu\text{m}$  infrared intensity and HI column density that follows a power-law for atomic hydrogen column densities of  $(3 - 20) \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ . Terebey and Fich (1986) have found a linear relation for two outer Galaxy regions close to the Galactic plane. Burton and Deul (1987) found that  $I_{100\mu\text{m}}$  is not related linearly with  $N_{\text{HI}}$ . They have used a large area containing low latitudes, extending 2.5 decades in  $N_{\text{HI}}$  and four decades in  $I_{100\mu\text{m}}$ . Similar correlations occur at higher latitudes. The flattening of their curve is explained by them by a non-negligible optical depth of HI. This effect is larger to the inner Galaxy ( $270^\circ < l < 90^\circ$ ) and near the Galactic plane ( $|b| < 5^\circ$ ). The data of Terebey and Fich, near  $b = 0^\circ$ , might also be influenced by non-negligible optical depths. The direction of the Magellanic Clouds is towards the inner Galaxy, but the longitude ( $l \approx 300^\circ$ ) and latitude ( $b \approx -35^\circ$ ) of the Clouds do not give us the impression that the optical depth plays an important role for these areas. Recently, de Geus (1988) has found a similar relation as us in the Ophiuchus region  $I_{100\mu\text{m}} \propto N_{\text{HI}}^2$ ; however he also found  $I_{60\mu\text{m}} \propto N_{\text{HI}}$ .

Besides optical depth effects there are various possibilities for the non-linearity: spatial variations in the gas-to-dust ratio and dust temperature effects. Terebey and Fich (1986) discussed that some properties might vary with latitude  $b$ . Stochastic variations in dust-to-gas ratio, dust temperature, dust properties, molecular contents are to be expected in different regions. Systematic variations with latitude are also expected as the stellar

density varies, resulting *e.g.* in variations in the radiation field. The molecular emission of the Galaxy is more concentrated towards the plane (Dame and Thaddeus, 1987; Burton and Deul, 1987) than the HI emission. Variations on large scale make it unlikely that the non-linear relation is due to the fact that  $N_{H_2}$  is correlated with  $N_{HI}$ . A primary possibility is a temperature effect, as the ratio  $I_{60\mu m}/I_{100\mu m}$  varies somewhat over the whole range of infrared intensities. Terebey and Fich also mention the combination of different effects that "might conspire to give a linear relation".

Fig. 5.1 shows that variations occur in the infrared-to-HI ratios. At  $b = -10^\circ$  we see that  $I_{100\mu m}/N_{HI}$  can vary from 0.7 – 1.5 in longitude only. This ratio is therefore not equal in all areas of the sky. Also note the variation of the dust temperature (hence  $I_{60\mu m}/I_{100\mu m}$ ), especially close to the Galactic plane. Infrared cirrus areas in our Galaxy and in M31 have typical ratios of 0.2 (see Low *et al.*, 1984; Terebey and Fich, 1986; Walterbos and Schwering, 1987). No clear relation of  $I_{100\mu m}/N_{HI}$  with temperature can be found from Table 4, nor in the paper by Boulanger and Perault, but the relation plays an important role for  $I_{100\mu m}$  and therefore for  $I_{100\mu m}/N_{HI}$ .

The non-linearity of  $I_{60\mu m}$  and  $I_{100\mu m}$  can be accounted for completely by the differences in temperature. The dust temperature varies from 20 to 25 K in the range of HI values  $(3 - 20) \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ . At these infrared wavelengths this gives just the intensity increase that we observe. At lower HI column densities (hence lower  $b$ ) the dust temperature does not vary. This is because there is no dust with temperatures below 20 K at these latitudes.

Because the infrared 60 and 100  $\mu m$  intensities and the HI column densities are related each in a different non-linear way, the dust temperature should follow the HI. Evidence that temperature plays a role comes from the relation between  $N_{HI}$  and visual extinction. For higher HI column densities and associated dust,  $\tau_{UV}$  increases, leading to relatively more photon trapping by dust and hence higher dust temperatures. If higher  $N_{HI}$  correspond to higher  $T_d$  the non-linearity is larger at 60 than at 100  $\mu m$ . The different non-linear relations between infrared intensity and the HI column density are then the result of temperature effects present on these large scales. This is not very clear from comparing Fig. 4.1 with Fig. 2.1, nor is it easy to quantify from Fig. 4.2. What is needed to dissolve the exact relation between  $I_{100\mu m}$  and  $N_{HI}$  is a systematic quantitative approach.

**Figure 7.** Galactic foreground colour excess maps. See pages 138 – 139.

Fig. 7.1. Galactic foreground  $E_{B-V}$ . Darker grey scales indicate a higher  $E_{B-V}$ , grey scales are chosen to enhance low values. Contours are at 0.02, 0.04, 0.06, 0.08, 0.10, 0.14, 0.18, 0.22, 0.26, 0.30 mag.

Fig. 7.2. Galactic foreground  $E_{B-V}$  grey scales map overlayed on the infrared 100  $\mu m$  contour map on the location of the LMC. Grey scale steps are at 0.04, 0.06, 0.08, 0.10, 0.12, 0.14, 0.16, 0.18, 0.20 mag.

Fig. 7.3. Galactic foreground  $E_{B-V}$  grey scales map overlayed on the infrared 100  $\mu m$  contour map on the location of the SMC. Grey scale steps are at 0.05, 0.06, 0.07, 0.08, 0.09, 0.10, 0.11, 0.12 mag. Note that the blob at  $b = -45^\circ$  is due to noise blow-up.

Fig. 7.1. Galactic foreground colour excess map

Fig. 7.2. LMC-foreground colour excess greyscale map and  $100\mu\text{m}$  contour map

## 6. The Galactic foreground extinction

We have calculated the colour excess in the Galactic foreground towards the Magellanic Clouds from the total hydrogen gas content  $N_H = N_{HI} + 2N_{H_2} \approx N_{HI}$  (assuming only HI to be present), following the relation of dust and gas as given by Bohlin *et al.* (1978) and Savage and Mathis (1979; and references therein)

$$N_H/E_{B-V} = 5.8 \times 10^{21} \text{ H-atoms cm}^{-2} \text{ mag}^{-1} \quad (6)$$

which was derived for the Solar Neighbourhood. Hence for the gas-to-dust mass-ratio derived in Section 4.5, the relation between  $E_{B-V}$  and  $M_d$  becomes

$$M_d/E_{B-V} = 2.3 \times 10^{-5} \text{ g cm}^{-2} \text{ mag}^{-1}. \quad (7)$$

Random errors in Equation 6 are estimated by Bohlin *et al.* (1978) at 6 %, while the unknown systematic errors in  $E_{B-V}$  probably dominate. Note the large scatter in Fig. 2 of Savage and Mathis, indicating large errors for individual points. The colour excess

map was obtained from rewriting Equation 6 to  $E_{B-V} \text{ (mag)} = 0.017 N_{HI} (10^{20} \text{ H-atoms cm}^{-2})$ .  $A_V$  and  $A_B$  can be deduced directly from the relations  $A_V = 3.1 E_{B-V}$  and  $A_B = 4.1 E_{B-V}$ ,  $A_V$  and  $A_B$  can be deduced directly. The so derived distribution of  $E_{B-V}$  is shown in Fig. 7, together with overlays of  $E_{B-V}$  with the  $100 \mu\text{m}$  infrared radiation on the position of Magellanic Clouds. For the relatively smooth SMC foreground (neglecting the dense blob discussed in Section 2.2) we find values  $E_{B-V} = 0.07 - 0.09 \text{ mag}$ , highest in the South (in declination; top in Fig. 7.3). The LMC foreground (on average  $E_{B-V} = 0.10 \text{ mag}$ ) shows significant variations, down to the resolution of  $48'$ .  $E_{B-V}$  varies from  $0.09 - 0.11$  towards the North (in declination; right in Fig. 7.2), via smaller values of  $0.07 - 0.09$  towards Greater 30 Doradus Region and the LMC-Bar up to  $0.13 - 0.17 \text{ mag}$  towards the southern area. The average  $E_{B-V}$  approaches the higher literature values given in Section 1 (Azzopardi and Vignean, 1977, for the SMC  $0.044 \pm 0.033$  and Brunet, 1975 for the LMC  $0.07 \pm 0.01$ ) and are somewhat higher but still within the errorbars of the values given by Koornneef (1984). The random errors are about 20 %, based on the uncertainties in the HI and the random error in Equation 6. A correction for the possible systematic error in the HI (15 % underestimate, see Section 2.2) will increase  $E_{B-V}$  by the same amount. In Section 7 the effects of a varying foreground are discussed for B and V data of the LMC.

The derivation of  $E_{B-V}$  from Galactic foreground stars (McNamara and Feltz, 1980) has the disadvantage that there are only a small number of these stars. They might not be far enough away to show all the Galactic foreground dust in the lines-of-sight towards the Clouds, in their spectra. The use of Magellanic Clouds stars (*e.g.* Isserstedt, 1975) gives rise to higher values of  $E_{B-V}$  and include all the foreground dust, but might be contaminated by Magellanic Cloud dust. The numbers that we obtain assume that the foreground dust is related well with atomic hydrogen and are unrelated to the Clouds and take into account all the foreground emission. On small scales a wide range of reddening values has been observed towards the LMC by Goudfrooij (priv. comm.).

Alternatively, we may take literature values of  $E_{B-V}$  to obtain the ratio  $N_{HI}/E_{B-V}$ . We assume that the McNamara and Feltz (1980) value of  $E_{B-V}$  is correct and use it with the HI foreground data. Then we derive  $16 \times 10^{21} \text{ (H-atoms cm}^{-2}/\text{mag)}$  for the LMC foreground and  $23 \times 10^{21}$  for the SMC foreground, 3 - 4 times higher than the Solar Neighbourhood value of Savage and Mathis (1979; see also Equation 6). For the dense cloud surrounding  $\rho \text{ Oph}$ , Savage and Mathis (1979) have given a value of  $15.4 \times 10^{21}$  roughly equal to the LMC foreground value in this case. For the dust and gas in the LMC (Koornneef, 1984)  $N_{HI}/E_{B-V}$  equals  $20 \times 10^{21}$ . However the large area that we have studied does not have such dense concentrations and we should expect a value rather close to the typical Galactic ratio. From these numbers we conclude that it is not possible to find a reliable value for  $N_{HI}/E_{B-V}$  from the known literature values for  $E_{B-V} < 0.04 \text{ mag}$  and the HI data.

Due to the relation  $A_V = 1.086 \tau_V$  the colour excess  $E_{B-V}$  is proportional to  $N_d$  (Mihalas and Binney, 1981) and therefore to  $N_{HI}$ , as we assume a constant gas-to-dust ratio. A problem between the connection of the infrared dust emission and the dust absorption in the visual region (see Savage and Mathis, 1979) might be that the value of  $E_{B-V}$  is determined mainly by small dust grains ( $a/\lambda < 10$ ) active as absorbers in B and V, while the larger dust grains do not contribute greatly to the colour excess; whereas the infrared emission (with  $\lambda_{IR} \approx 100 \lambda_B$ ) is mainly caused by these larger grains ( $a/\lambda \approx 1$ ). If

this is the case a larger scatter would be expected in the relation between  $N_{HI}$  and  $E_{B-V}$ . The good relation between these quantities shows that the grains are spatially related.

Infrared emission is emitted by dust, while dust also gives rise to extinction. To quantify the relation between infrared emission and  $E_{B-V}$ , we use Equations 3, 5 and 6 to derive the ratio  $E_{B-V}/I_{100\mu m}$  (MJy/sr). This relation can be expressed in terms of the dust temperature  $T_d$  and the column density  $N_d$ , as

$$\begin{aligned} E_{B-V}/I_{100\mu m} &= (5.8 \times 10^{21} \alpha_{100\mu m} H I^{\beta_{100\mu m}})^{-1} \\ &= (5.8 \times 10^{21} (N_{HI}/<N_{HI}/N_d>) m_{HI} \kappa_\nu B_\nu(T_d))^{-1}. \end{aligned} \quad (8)$$

We find  $E_{B-V}/I_{100\mu m} = 0.029 \pm 0.015$  (mag) / (MJy/sr) for the LMC foreground and  $0.06 \pm 0.03$  for the SMC foreground. These values, together with  $A_V$  and  $A_B$  are given in Table 3. The errors are based on the possible variation in the foreground infrared and HI emission over the objects. The relation of  $A_B/I_{100\mu m}$  for the LMC is very close to the relation derived by de Vries (1986). The SMC relation is clearly higher, which is the result of the relatively low infrared emission compared to HI.

## 7. Implications of the extinction by foreground dust on Magellanic Clouds studies

The Galactic foreground dust and infrared properties are used to study absorption influences on visual and ultraviolet data of the Magellanic Clouds. It has also been used to estimate the foreground infrared emission in the direction of the Magellanic Clouds (see Section 4). Comparisons between Galactic foreground and Cloud infrared and dust data will be dealt with in Chapter VI.

We have compared the LMC  $E_{B-V}$  data of Isserstedt (1975) and Isserstedt and Kohl (1984) with the foreground dust emission. The data of Isserstedt consist of LMC-stars with known colours that can be used to derive the colour excess. Isserstedt applied a constant foreground extinction correction of 0.07 mag. Our data show the LMC-Bar and the Greater 30 Doradus Region to be in relative weak HI foregrounds and therefore dust-free areas compared to the outer areas such as Shapley's Constellation III and the N 11 complex. The high values for  $E_{B-V}$  in 30 Doradus ( $> 0.14$  mag) must therefore be explained mainly by an internal LMC dust component and might be over-corrected for foreground dust by 0.03 mag. Note that we compare numbers in this section relative to the average foreground. The radiation from stars at the outer area, and especially in the southern part, of the LMC is more absorbed by Galactic foreground dust and should therefore still have a contribution of about 0.04 mag in  $E_{B-V}$  due to the varying foreground. There are a large number of stars visible in the outer area, with low colour excesses ( $< 0.08$  mag); a correction for the foreground would decrease  $E_{B-V}$  by a factor two. Obviously, we do not expect stars in the LMC to have  $E_{B-V} < 0.04$  mag. There are some reasons why they are observed. The number of stars used by Isserstedt and Kohl (1984) is lower in the South, where the foreground  $E_{B-V}$  is higher. The spectral type of the stars has to be known very accurately. This could result in systematic errors in  $E_{B-V}$ . A clear indication for this is the presence

of stars with  $E_{B-V} = -0.10$  in Isserstedt's (1985) diagram. According to Isserstedt, the large number of stars with reddening values less than 0.04 mag indicates that there are variations in the foreground on small spatial scales. Application of the varying foreground will result in an adjustment to the LMC dust-to-gas relation ( $E_{B-V}/N_H$ ) of areas with non-average  $E_{B-V}$ ; in the Greater 30 Doradus Region the ratio would become higher and in the South smaller.

Studies of the spatial distribution of the interstellar extinction curve of the LMC have been performed by Fitzpatrick (1985, 1986). From the data he obtains an "average" LMC extinction curve  $A_{\lambda-V}/E_{B-V}$  which is more similar to the Galactic one (Savage and Mathis, 1979) than the 30 Doradus curve (Koornneef and Code, 1981). The latter curve, the "normal" LMC curve, has a weaker 2200 Å feature and rises steeper in the ultraviolet than the Galactic curve. Under the assumption that the foreground absorption and contribution to the colour excess do not vary, Fitzpatrick concludes that his new LMC curve is a better average than the 30 Doradus curve. This point has to be reconsidered due to the variation in the foreground. Depending on the assumed average extinction, the lower absorption towards the 30 Doradus region means that the foreground correction applied there is too high, while in the other areas the correction is too low. As a consequence, extinction curve differences between the 30 Doradus regions and other parts of the LMC are artificially enhanced, so that after a spatially dependent correction, the 30 Doradus and the LMC's "average" curve will in fact approach each other. As the lines-of-sight towards the reference stars have to be taken into account as well, this complicates the (small scales) interpretation of spatially varying absorption. We see that the directions towards a part of the LMC-Bar and the Greater 30 Doradus region are most suited to eliminate the influence of the Galactic foreground extinction.

The "normal" SMC extinction curve (Prévot *et al.*, 1984) is even more extreme. The 2200 Å feature is missing entirely and the ultraviolet rise is even steeper. Lequeux *et al.* (1984) have shown that three SMC stars, Sk 124, Sk 191 and especially Sk 143, have extinction curves which resemble the average Galactic one better. From our data we find no evidence for expecting a higher foreground contribution to any of these stars than to others with a "normal" SMC extinction curve.

## 8. Conclusions

The Galactic infrared and dust foreground towards the Magellanic Clouds has been discussed for the IRAS bands. The stellar foreground in the infrared is non-significant except at 12  $\mu\text{m}$ , where it contributes 3 % of the total integrated flux density of the LMC and 10 % of the integrated flux density of the SMC.

The cirrus infrared foreground, which consists of large scale cool dust, is clearly non-planar and shows structure on all scales down to the resolution limit. A subtraction of the HI-predicted infrared foreground from maps of the LMC gives a better quantitative result than fitting a simple foreground plane. At 60  $\mu\text{m}$  the cirrus foreground contains 10 – 20 % of the integrated flux densities of the Clouds over the same area. The percentage is 30 – 40 % for the 100  $\mu\text{m}$  band. The higher percentages occur for the SMC which is fourteen times weaker than the LMC in the infrared. The foreground intensities towards the SMC are 0.3 – 0.6 times those for the LMC foreground.

The Galactic foreground infrared intensities  $I_{60\mu\text{m}}$  and  $I_{100\mu\text{m}}$  are well-correlated with  $N_{\text{HI}}$ , but the correlation is non-linear. At 60 and 100  $\mu\text{m}$  the relation goes as a power-law with exponents of about 3.5 and 2.0 respectively. The global ratio  $I_{100\mu\text{m}}/N_{\text{HI}}$  has an average value of  $0.6 \pm 0.2$ . In general the ratio is not constant and temperature effects are the main reason for the non-linearities.

We obtain a high average gas-to-dust ratio. The explanations for this high ratio are the uncertainties in the dust parameters and the underestimate of the dust column densities. This high gas-to-dust ratio does not influence the removal of the infrared foreground towards the Clouds.

We have showed that in the infrared, visual and ultraviolet wavelength regimes positionally dependent foreground extinction corrections have to be applied for the LMC. The  $E_{B-V}$  range of the foreground is 0.07 – 0.17 mag towards the LMC and 0.07 – 0.09 towards the SMC. These values are close to the highest values obtained from stellar photometry. Towards the LMC  $E_{B-V}$  probably varies on scales smaller than 48'; especially towards 30 Doradus and the LMC-Bar where  $E_{B-V}$  is lower than average. The foreground is rather smooth towards the SMC. Observations of Isserstedt and Kohl (1984) and Fitzpatrick (1985, 1986) likewise contain supporting evidence for these variations in  $E_{B-V}$ .

## Chapter V

### OVERALL INFRARED PROPERTIES OF THE MAGELLANIC CLOUDS

#### 1. Introduction

Of all galaxies the Magellanic Clouds are the closest to the Milky Way galaxy. Because of their proximity they are ideal objects to study galactic structure in detail, while their large scale and integrated properties can also be determined. For most other galaxies only integrated data are available, especially in the infrared which has been surveyed only recently, by IRAS (IRAS, 1985a). Thus, a study of the global and integrated properties of the Magellanic Clouds as well as their detailed structure will provide reliable clues to the interpretation of infrared emission of more distant galaxies.

Detailed maps of the emission from the Magellanic Clouds as observed by IRAS are presented in Chapter II (SMC) and Chapter III (LMC). In this chapter we discuss the global and integrated infrared properties of the Magellanic Clouds. In Section 2 we describe the maps that are used. Section 3 contains a discussion of the integrated flux densities and spectra. The infrared size and the luminosity of each Cloud are also discussed. Section 4 contains a discussion of the global infrared morphology and the line-of-sight distribution of dust temperatures. A comparison of infrared emission with the  $H\alpha$  supergiant shells is presented and the strength of the interstellar radiation field is estimated. Section 5 contains a comparison of the infrared maps with ultraviolet,  $H\alpha$  and radiocontinuum data. Conclusions are given in Section 6.

#### 2. Data presentation and data handling

The infrared observations used in this chapter were obtained with the Infrared Astronomical Satellite (IRAS) during its mission in 1983. For the derivation of the integrated properties we have used low resolution maps such as the  $16\mu\text{m}$  extended emission "Skyflux" image plates (IRAS, 1985a), the "Spline-I" maps (van Albada *et al.*, 1985) and maps of the "Zodiacal Observations History File" (IRAS-ZOHF; see Chapter IV). For the SMC area a special  $5^\circ \times 5^\circ$  "IRAS Survey Co-add" was made, similar to the method as described in Chapter II (the LMC is too large for such an approach), and finally we used "IRAS Additional Observations" (AOs) of the DPM-type. Note that only the IRAS AO DPM-maps consist of independent observations and that all the other data are reprocessed versions of the IRAS Survey data (IRAS, 1985a). The AO data and their reduction have been fully described in Chapters II (SMC) and III (LMC). To compare IRAS data (with resolutions of  $1' \times 5' - 3' \times 5'$ ) with those at other wavelengths and lower resolutions, it is necessary to convolve the IRAS data to lower resolutions. This is done by first applying a linear deconvolution with a theoretical beamprofile (calculated as described by Braun, 1985) using a spatial frequency taper truncated at the 1 % level. The highest gaussian resolution possible has a HPBW of  $6.9''$  in the cross-scan direction and  $1.1'', 1.1'', 2.2''$  and

4/3 in the scan direction at 12, 25, 60 and 100  $\mu\text{m}$ . At the distance of the Magellanic Clouds 1' corresponds to 15 resp. 18 pc. At full resolution only the 30 Doradus peak is strong enough to produce dynamic range problems in the 25  $\mu\text{m}$  map; it results in low level sidelobes. The low resolution data were obtained by convolution to resp. 8' and 15' gaussians (corresponding to a linear resolution of about 135 and 250 pc; the latter is identical to the IRAS in-scan resolution on M31; see Walterbos and Schwope, 1987). By averaging the two resp. three different scan-direction maps (see Chapters II and III) we increase the signal-to-noise ratio in the maps (at the SE end of the LMC-Bar, only the NS-scanned map was used due to an unacceptable stripe level in the EW-scanned map; see Chapter III). Especially for the SMC the convolution and map-averaging procedure gave a significant improvement in the 12 and 25  $\mu\text{m}$  bands. We estimate that the relative photometric uncertainties in the maps are reduced from 10 % to about 5 %. The absolute photometric uncertainty does not change. The 8' resolution maps are presented in Fig. 1 (8'0 x 8'0 around the LMC) and Fig. 2 (4'8 x 4'8 around the SMC).

### 3. Integrated infrared properties of the Magellanic Clouds

#### 3.1. Flux densities and spectra

We have determined the integrated infrared flux densities as follows. For various representations of IRAS maps, pixel intensity values were summed in areas covered by the two Clouds, which were identical for all four infrared bands. Some of these maps have reduced, relative backgrounds (IRAS AO DPM-maps; Survey Co-add; ZOHF maps; see Chapter II and IRAS, 1985a), others have an absolute background level (IRAS Skyflux; Spline-I). A mean background contribution is then subtracted by extrapolation of the "background sum" to the "zero-area sum". This method is illustrated in Fig. 3 (LMC; ZOHF) and 4 (SMC; AO). After multiplying these sums by normalisation factors, by the pixel size and dividing the in-band fluxes so obtained by the bandwidth, integrated flux densities for these objects were obtained ( $f_\nu = \int_{\text{area}} I_\nu d\Omega \approx \Delta\Omega_{\text{pix}} \sum_{\text{pix}} I_\nu$ ). This method gives us the integrated values of Table 1 for the LMC and Table 2 for the SMC. The errors presented in these tables are obtained from the flux density determination and do not incorporate the absolute photometric accuracy.

In order to remove the correct background, the area under consideration has to be larger than the Clouds. The method of background subtraction works well for a flat background. We have used a summing area that was primarily based on the optical size (de Vaucouleurs *et al.*, 1976), adjusted by inspection of the infrared maps and by the change in steepness of the slope in the sum-figures. For the LMC the derived flux densities assume a square box size of 8°. For the SMC we find that a size of 2.5° at 60 and 100  $\mu\text{m}$  is sufficient. The integrated flux densities at 12 and 25  $\mu\text{m}$  are more difficult to determine, because there is some structure present beyond the initial 2° x 2° size limit. With an area of 4° x 4° the whole wing is included, but a much larger spread in the determined integrated flux densities result ( $f_{12\mu\text{m}} = 160 \pm 160 \text{ Jy}$ ,  $f_{25\mu\text{m}} = 420 \pm 100 \text{ Jy}$ ; only a 10 % increase at 60 and 100  $\mu\text{m}$ ). In the LMC a size-increase from 6° to 8° gives a similar, but less pronounced trend. No accurate flux densities can be obtained from the IRAS Skyflux images at 12 and 25  $\mu\text{m}$ .

**Figure 1.** Infrared maps of the Large Magellanic Cloud at a resolution of  $8'$ . Coordinates are for equinox 1950. All LMC maps in this chapter cover an area of  $8.0^\circ \times 8.0^\circ$  centered on  $05^h24^m$  and  $-69^\circ00'$ . See pages 148 – 149.

In the  $12\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $0.074 - 0.19$  and from  $0.26 - 0.56$ ; darker grey scales indicate higher intensities. Contours are at  $0.22, 0.37, 0.74, 1.1, 1.5, 3.0, 4.5, 5.9, 7.4, 15, 37, 51\ \text{MJy/sr}$ .

In the  $25\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $0.097 - 0.48$  and from  $0.68 - 1.5$ ; darker grey scales indicate higher intensities. Contours are at  $0.58, 0.97, 1.9, 2.9, 3.9, 7.8, 12, 16, 19, 39, 97, 190, 330\ \text{MJy/sr}$ .

In the  $60\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $0.6 - 1.0$ , from  $1.4 - 2.9$  and from  $3.9 - 9.7$ ; darker grey scales indicate higher intensities. Contours are at  $3.9, 7.8, 12, 16, 25, 31, 39, 58, 78, 160, 270, 390, 580, 1200\ \text{MJy/sr}$ .

In the  $100\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $1.0 - 2.5$ , from  $3.5 - 7.5$  and from  $10 - 25$ ; darker grey scales indicate higher intensities. Contours are at  $10, 20, 30, 40, 65, 80, 100, 150, 200, 400, 700, 1000, 1300\ \text{MJy/sr}$ .

**Figure 2.** Infrared maps of the Small Magellanic Cloud at a resolution of  $8'$ . Coordinates are for equinox 1950. All SMC maps in this chapter cover an area of  $4.8^\circ \times 4.8^\circ$  centered on  $00^h58^m$  and  $-73^\circ00'$ . See pages 150 – 151.

In the  $12\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $0.074 - 0.19$  and from  $0.26 - 0.56$ ; darker grey scales indicate higher intensities. Contours are at  $0.22, 0.37, 0.74, 1.1, 1.3\ \text{MJy/sr}$ .

In the  $25\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $0.097 - 0.48$  and from  $0.68 - 1.5$ ; darker grey scales indicate higher intensities. Contours are at  $0.58, 0.97, 1.9, 2.9, 3.9, 5.8, 6.1\ \text{MJy/sr}$ .

In the  $60\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $0.19 - 0.97$  from  $1.4 - 2.9$  and from  $3.9 - 12$ ; darker grey scales indicate higher intensities. Contours are at  $1.2, 1.9, 3.9, 9.7, 16, 21, 27, 33, 39, 46\ \text{MJy/sr}$ .

In the  $100\ \mu\text{m}$  map grey scales are linear with a saw-tooth from  $0.5 - 2.5$ , from  $3.5 - 7.5$  and from  $10 - 30$ ; darker grey scales indicate higher intensities. Contours are at  $3, 5, 10, 25, 40, 55, 70, 74\ \text{MJy/sr}$ .

**Figure 3.** LMC flux density integration using IRAS ZOHF data. The axes are the number of pixels in the integration, centered on the Cloud (with pixel size  $\Delta\Omega = 15' \times 15'$ ), horizontally and the sum of the pixel intensities (MJy/sr) vertically. The size of the LMC is about  $8^\circ \times 8^\circ$ , which is indicated in the figures. The extrapolation of the background sum to the zero-area sum  $S_\nu$  (MJy/sr) corrects for this background. The final flux density of the LMC is found from  $(f_\nu/\text{Jy}) = 10^6 (S_\nu/\text{MJy sr}^{-1}) (\Delta\Omega/\text{sr})$ .

**Figure 4.** SMC flux density integration using IRAS AO data. The axes are the number of pixels in the integration, centered on the Cloud (with pixel size  $\Delta\Omega = 3' \times 3'$ ), horizontally and the sum of the pixel intensities ( $10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ ) vertically. The size of the SMC is about  $2.5 \times 2.5$ , which is indicated in the figures. The extrapolation of the background sum to the zero-area sum  $S_\nu$  ( $10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ ) corrects for this background. The final flux density of the LMC is found from  $(f_\nu/Jy) = 10^{+18} (S_\nu/10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}) (\Delta\Omega/\text{sr}) (\Delta\nu/\text{Hz})^{-1}$ .

## Notes to Tables 1 and 2:

First some general remarks: All flux densities assume an intrinsic source spectrum  $f_\nu \propto \nu^{-1}$ ; only a planar foreground removal has been done; i.e. detailed diffuse and stellar emission has not been subtracted. Note that  $1 \text{ MJy/sr} = 305 \text{ Jy}/(^{\circ})^2 = 85 \text{ mJy}/(')^2 = 24 \text{ } \mu\text{Jy}/('')^2$ .

- a) The AO value was calculated by weighing the two independent full-resolution LMC maps, resp. the three SMC maps with the inverse of the determined error. Errors in the AO average are based on the flux determination, and not on the absolute photometry. The relative errors in the determination add up to 2 – 3 % for the LMC and 3 – 8 % for the SMC. Individual AO errors are 1.5 times higher than the LMC-average and 1.8 times higher than the SMC-average. Smoothed (8' and 15') AO's give about the same results as the average values in this table. The resolution of these maps is about 0.8 x 4.8, 0.8 x 4.8, 1.5 x 4.8 and 3' x 5' in the 12, 25, 60 and 100  $\mu\text{m}$  bands.
- b) We have used only HCON-1 of Skyflux. The relative errors are considerably larger (7 – 17 %) than for AO maps. The 12 and 25  $\mu\text{m}$  integrations in Skyflux were much hindered by a bad zero-level, and bad areas of field overlap. The 60 and 100  $\mu\text{m}$  points are very similar to the AO determined values (1.0 – 1.1 times). The resolution of these data is 4' – 6'.
- c) The calibration of the Groningen-IRAS Spline-I product (van Albada *et al.*, 1985) was corrected with a factor of 0.7 (Deul, priv. comm.; see Walterbos and Schwoering, 1987). We have used the 50° x 50° fields produced by Braun, Walker and Deul (priv. comm.) at Leiden Observatory. The Spline-I product only contains 60 and 100  $\mu\text{m}$  data. For both galaxies the 60  $\mu\text{m}$  point is about 0.82 of the AO average, while the 100  $\mu\text{m}$  point is very similar (0.98 – 1.05). The relative errors in this determination are much larger than in the AO data (8 – 15 %). The resolution of these data is 10'.
- d) The Zodiacal Observations History File (ZOHF; IRAS, 1985a) were corrected for Zodiacal emission by Deul (see Deul and Wolstencroft, 1988). The LMC values are 1.2 – 1.3 times higher than the AO values. The SMC values are 1.4 times higher at 60 and 100  $\mu\text{m}$  up to 2.1 – 3.6 at 12  $\mu\text{m}$ . The relative error in the determination for the LMC is 4 – 13 %. The resolution of these data is 30'. The SMC ZOHF values are not given because they cannot be determined with enough accuracy. They give errors of 10 – 58 % and are 1.4 – 3.6 times higher than the AO values. Note the strong striping at 12 and 25  $\mu\text{m}$ , especially at the position of the SMC (see Chapter IV). On the SMC we Co-added IRAS Survey data, which give the results as presented in this table. The relative errors are 4 – 16 %. The Co-add has a resolution similar as the AO data (see note a). The Co-added 25  $\mu\text{m}$  point is 0.75 times lower than any other value; while the other bands correspond very well: 0.95 – 1.1 times the AO values.
- e) The numbers are from Rice *et al.* (1988a). Their 12  $\mu\text{m}$  point is 0.4 – 0.6 times the AO, 25  $\mu\text{m}$  is 0.7 – 0.8 times the AO and 60 and 100  $\mu\text{m}$  are about equal (0.9 – 1.1).
- f) The average background intensity (produced by the Galactic foreground) was estimated from the Skyflux (HCON-1, -2 and -3) maps. At 12 and 25  $\mu\text{m}$  they contain Zodiacal emission. Similar values are found at the South Ecliptic Pole for the Zodiacal emission by Deul and Wolstencroft (1988). At 60  $\mu\text{m}$  the Skyflux maps contain both Zodiacal and Galactic diffuse emission and at 100  $\mu\text{m}$  they contain only Galactic diffuse emission. The intensity values have been converted to absolute flux density levels by using a size of 8° x 8° on the LMC and 3° x 3° on the SMC. Note that these absolute values are 52 – 53 times higher than the LMC flux values at 12 and 25  $\mu\text{m}$  and 0.9 – 1.9 times higher at 60 and 100  $\mu\text{m}$ . For the SMC these ratios are 200 – 220 and 1.4 – 3.2.

For comparison reasons, we have determined the 12 and 25  $\mu\text{m}$  flux densities in another way. As the sizes of both Clouds are larger at 100  $\mu\text{m}$  than at 12 and 25  $\mu\text{m}$  we assume that the infrared radiation is coming only from the part of the Clouds for which  $I_{100\mu\text{m}} > I_{\text{cut-off}}$ . We have set a 100  $\mu\text{m}$  cut-off limit in the AOs at various values ranging from 5.0 to 0.5 MJy/sr. If we sum the infrared data in these areas we obtain flux densities of 150 – 220 Jy at 12  $\mu\text{m}$  and 370 – 440 Jy at 25  $\mu\text{m}$  for the SMC. The values for the AO maps as given in Table 2, are found at a cut-off value of 2.7 MJy/sr in both bands. In the same way we obtain flux densities for the LMC at 12  $\mu\text{m}$  of 4400 – 4800 Jy and at 25  $\mu\text{m}$  of 9950 – 10300 Jy resp. The AO values in Table 1, are equal to a 100  $\mu\text{m}$  intensity cut-off of 0.5 MJy/sr.

The values determined from the different map sets correspond very well for the LMC in all four bands. The two LMC and three SMC full resolution AOs are very similar and a good average is derived. The Spline-I 60  $\mu\text{m}$  point is somewhat low but it may need recalibration (Walterbos and Schwering, 1987). The Skyflux 60 and 100  $\mu\text{m}$  values are very similar, but since we have checked the AO calibration with the aid of the AO-Skyflux pixel-to-pixel scatter diagrams, they are not expected to be very different. The LMC values for the ZOHF are 1.2 – 1.3 times larger in all bands. This can be explained by the larger area that is covered by those maps, and is an indication for the presence of some structure in that larger area (which must be part of the LMC or Galactic foreground at 60 and 100  $\mu\text{m}$ ; at 12 and 25  $\mu\text{m}$  some residual stripes are present in the ZOHF maps). For the SMC the situation is somewhat more complicated. For the 12 and 25  $\mu\text{m}$  data the error may be larger due to a non-uniform background (partial Wing exclusion and possible extended emission). But the values are very similar and correspond well to the Co-added Survey data at full IRAS resolution of the SMC (less well at 25  $\mu\text{m}$ ). The SMC is not bright enough to produce a good estimate from the ZOHF data. The values obtained from these data are several times higher than the AO values due to the residual stripes that dominate at the position of the SMC. The low resolution 8' and 15' AO data confirm the observed higher resolution AO values.

The flux density values obtained by Rice *et al.* (1988a) are lower (0.4 – 0.8) than the AO values for both Clouds. The 60 and 100  $\mu\text{m}$  flux densities are between 0.9 and 1.1 times the AO values. Although we do not know the details of Rice *et al.*'s determination, the discrepancies show the difficulties in determining total flux densities of such extended objects. A part of the differences might be explained by the fact that the Survey map flux densities in the 12 and 25  $\mu\text{m}$  bands of the fainter sources are lower by as much as 50 % compared to the pointed AO observation measurements (see Rice *et al.*, 1988a). As many weak sources are present in these galaxies this can add up to a reasonable total flux density.

The difference between our AO derived integrated flux densities and the flux densities as derived by Rice *et al.* from IRAS Survey Co-adds might be the result of calibration differences (*i.e.* differences in the intensity scaling factor) or differences in the adopted background or both. Let us consider the first option: Rice's Co-add scaling is 0.4 – 0.8 at 12 and 25  $\mu\text{m}$  compared to the AOs. We have checked the AO's LMC intensity levels with the Skyflux values and they resemble each other quite well in all four bands. For the SMC this was not possible at 12 and 25  $\mu\text{m}$  (see Chapter II). Also the point sources that were compared with the IRAS Point Source Catalogue (IRAS PSC; IRAS 1985a) correspond

quite well, especially stars at  $12\ \mu\text{m}$ , which indicates a good AO scaling. Due to the larger differences with the IRAS PSC entries in the 60 and  $100\ \mu\text{m}$  bands we would expect a larger error in those bands. Some bright LMC foreground SAO stars in the LI-LMC list are 20 % weaker at  $12\ \mu\text{m}$  than in the PSC (Chapter IV). We believe that this effect occurs only at the highest fluxes, but if it were more common it would explain a higher integrated flux density instead of a smaller one.

A more likely possibility is a difference in background between the AO maps and Rice *et al.*'s Co-added maps. Qualitatively, the differences in the 12 and  $25\ \mu\text{m}$  bands of our integrated flux densities with those of Rice *et al.* correlate with the background slope in Fig. 3 and 4. The determined background slopes of Fig. 4 (SMC) are caused by background levels of 0.019 at 12, 0.012 at 25 and 0.005 MJy/sr at 60 and  $100\ \mu\text{m}$ . Variations in the LMC-background slopes can explain only 10 % flux density variations. We tried to obtain Rice's 12 and  $25\ \mu\text{m}$  values from the AO map sets, but no unique background slope could be fitted to the various maps. The absolute infrared background level at the positions of the SMC and LMC, as determined from Skyflux images are given in Tables 1 and 2. The differences between the results obtained by Rice *et al.* and by us can be accounted for by background differences of 0.1 MJy/sr (LMC;  $8^\circ \times 8^\circ$ ) and 0.07 MJy/sr (SMC;  $2^\circ \times 2^\circ$ ); this is less than 1 % of the actual background emission. These suggested background differences are too high to be explained by the AO zero-level uncertainties as given in Chapters II and III. Those uncertainties predict 10 % flux errors in all bands for the LMC and 2 – 10 % for the SMC. Note that the 12 and  $25\ \mu\text{m}$  integrated flux densities for the Clouds are less than 1/50 of the absolute background for the LMC and about 1/200 of that for the SMC.

Flux densities derived for extended objects based on single AO data, or any other single-map infrared data, should be considered with great care. The agreement between the different map sets gives us confidence in the reliability of the here derived values. \* Both the problems mentioned by Rice *et al.* for weak sources, and the extensive Zodiacal foreground are probably responsible for the difference in the flux densities at 12 and  $25\ \mu\text{m}$  derived by them and by us. The best estimate for the integrated infrared flux densities is obtained from the average of the AO and ZOHF values for the LMC and the average of the AO and Co-add values for the SMC, weighted by the inverse of the measured uncertainties. These values are given in Table 3, as "Average observed flux densities".

In Table 3 we summarize the observed integrated infrared properties for the two Magellanic Clouds. We estimate the error in the absolute photometry to be 10 % (see Section 2). After the flat-background correction explained above, the observed flux densities were corrected for local variations (by stars and diffuse Galactic foreground; Chapter IV). The "Average observed" values of Table 3 were already corrected for a planar background. This is correct at 12, 25 and  $60\ \mu\text{m}$ ; at  $100\ \mu\text{m}$  the SMC background is also planar, but the LMC background is increased by 20 % due to small scale structure especially at the southern side of the Cloud (Chapter IV). Colour-correction factors have been calculated from the "Average Observed" integrated spectrum using Table VI.C.6 of

---

\* The values given earlier by Israel and Schwering (1986) were based on the same AO data, but corrected for stellar foreground emission and with a preliminary calibration (May-1984), and a less well corrected background; they are somewhat lower in all four bands (0.7 – 0.9 x).

Table 3. Observed integrated infrared properties of the Magellanic Clouds.

Property	Unit	LMC	SMC
General characteristics <sup>a)</sup> :			
Distance $D$	kpc	53	63
Linear/angular scale	pc/'	15	18
Optical diameter	°	10.8	4.7
Absolute $V$ -magnitude	mag	-18.5	-16.8
Average observed flux densities <sup>b)</sup> :			
12 $\mu\text{m}$	Jy	4980 $\pm$ 500	161 $\pm$ 16
25 $\mu\text{m}$	Jy	10800 $\pm$ 1100	363 $\pm$ 36
60 $\mu\text{m}$	Jy	102000 $\pm$ 10000	7100 $\pm$ 710
100 $\mu\text{m}$	Jy	221000 $\pm$ 22000	13900 $\pm$ 1400
Galactic foreground flux densities <sup>c)</sup> :			
		Stars / Diffuse	Stars / Diffuse
12 $\mu\text{m}$	Jy	130. / 3500	17. / 300
25 $\mu\text{m}$	Jy	51. / 3000	3.5 / 260
60 $\mu\text{m}$	Jy	3.2 / 10000	0.4 / 1400
100 $\mu\text{m}$	Jy	0.0 / 81000	0.0 / 5800
Clouds 100 $\mu\text{m}$ flux density at other distances <sup>d)</sup> :			
3 Mpc (M81 group)	Jy	68.	6.4
15 Mpc (Virgo cluster)	Jy	2.7	0.25
Limits for detection in the IRAS PSC <sup>d)</sup> :			
12 $\mu\text{m}$ ( $f_\nu > 0.25$ Jy)	Mpc	7.5	1.6
25 $\mu\text{m}$ ( $f_\nu > 0.25$ Jy)	Mpc	11.	2.4
60 $\mu\text{m}$ ( $f_\nu > 0.40$ Jy)	Mpc	27.	8.4
100 $\mu\text{m}$ ( $f_\nu > 1.00$ Jy)	Mpc	25.	7.4
IRAS Colour correction factors <sup>e)</sup> :			
12 $\mu\text{m}$	$f_{\text{true}}/f_{\text{quoted}}$	1.00	1.02
25 $\mu\text{m}$	$f_{\text{true}}/f_{\text{quoted}}$	1.05	1.07
60 $\mu\text{m}$	$f_{\text{true}}/f_{\text{quoted}}$	1.01	1.01
100 $\mu\text{m}$	$f_{\text{true}}/f_{\text{quoted}}$	1.00	1.00
Foreground and Colour corrected ("Recommended") flux densities <sup>f)</sup> :			
12 $\mu\text{m}$	Jy	4850 $\pm$ 500	147 $\pm$ 16
25 $\mu\text{m}$	Jy	11300 $\pm$ 1100	385 $\pm$ 36
60 $\mu\text{m}$	Jy	103000 $\pm$ 10000	7170 $\pm$ 710
100 $\mu\text{m}$	Jy	208000 $\pm$ 22000	13900 $\pm$ 1400

Table 3, continued.

Property	Unit	LMC	SMC
Average infrared surface brightness <sup>a)</sup> :			
12 $\mu\text{m}$	MJy/sr	0.17	0.028
25 $\mu\text{m}$	MJy/sr	0.40	0.073
60 $\mu\text{m}$	MJy/sr	3.7	1.4
100 $\mu\text{m}$	MJy/sr	7.4	2.6
Integrated flux density of discrete infrared sources <sup>b)</sup> :			
12 $\mu\text{m}$	Jy / %	677 / 14	51 / 35
25 $\mu\text{m}$	Jy / %	2124 / 19	182 / 47
60 $\mu\text{m}$	Jy / %	14925 / 14	1421 / 20
100 $\mu\text{m}$	Jy / %	26252 / 13	2283 / 16

## Notes to Table 3:

- a) The distance is taken from Humphreys (1984), the optical diameter and the absolute visual magnitude are taken from de Vaucouleurs *et al.* (1976).
- b) The quoted IRAS flux densities assume a  $f_\nu \propto \nu^{-1}$  intrinsic source spectrum. The LMC average is the AO and ZOHF value, weighted by the reciprocal uncertainties. The SMC average is the AO and Co-add value, weighted by the reciprocal uncertainties. The error is set equal to the 10 % photometric error.
- c) These Galactic foreground values are taken from Chapter IV and include an extra correction (of 20 %) for a non-planar foreground at 100  $\mu\text{m}$  at the position of the LMC.
- d) The Clouds' flux densities at the distance of the M81-group and the Virgo cluster are given. Limits for detection of sources with the same infrared flux density as the Clouds are also given.
- e) These colour correction factors have been obtained from the average observed IRAS flux densities.
- f) These flux densities have been obtained by subtracting the total foreground stellar and diffuse contributions and multiplying the result by the colour correction factors; they are the true flux densities of the Magellanic Clouds.
- g) The average surface brightness is calculated from the flux densities and the surface area determined from the optical diameter as given in this table. The LMC values are 5.8 times higher than the SMC values at 12 and 25  $\mu\text{m}$  and 2.7 times at 60 and 100  $\mu\text{m}$ .
- h) The sum of all the discrete sources from Chapters II and III are given, together with the fraction of the total flux density.

IRAS (1985b). To obtain the true flux density values these factors have been multiplied with the observed integrated flux densities. The final "Recommended" flux densities are listed in the table. Note that colour-correction factors depend on the resolution; here they are based on the integrated flux densities. Hence they are only good average values and are not necessarily correct for individual areas in the infrared maps.

Table 3 also contains the 100  $\mu\text{m}$  flux densities the Clouds would have if they were at distances of 3 Mpc (in the M81 group) or 15 Mpc (in the Virgo cluster). The SMC would be below the IRAS PSC detection limit at the latter distance, even for IRAS Co-added Survey data (which have a detection limit which is 1.3 – 4 times better than the IRAS PSC, with the smallest increase at 100  $\mu\text{m}$ ; Caspers, priv. comm.). Furthermore we have calculated the detection limit of the Clouds for the IRAS PSC. Galaxies with the same infrared luminosity as the LMC are detectable at distances up to 27 Mpc, four times farther than those with the same luminosity as the SMC.

The integrated, foreground and colour corrected infrared spectra of both Clouds are shown in Fig. 5, together with the spectra of M31 (Walterbos and Schwering, 1987) and NGC 4449 (Hunter *et al.*, 1986); the two latter spectra are both scaled to the distance of the LMC. The LMC (with a diameter of 7.8 kpc) is, about 12 times more luminous in the infrared than the SMC (with a diameter of 2.6 kpc). A smaller difference is still present after we correct for the different sizes. The average surface brightness, given in Table 3, is 5.8 times higher in the LMC than in the SMC at 12 and 25  $\mu\text{m}$  and 2.7 times at 60 and 100  $\mu\text{m}$ . At 60  $\mu\text{m}$  the LMC has the same infrared luminosity as the much larger Andromeda spiral galaxy M31 (60 kpc diameter). Note also that, for  $\lambda > 12 \mu\text{m}$  NGC 4449 (9.4 kpc diameter) is brighter than M31. NGC 4449 has a four times higher infrared luminosity than the LMC, and a 3 times higher surface brightness. At 25 and 60  $\mu\text{m}$  M33 (not shown in Fig. 5; see Rice *et al.*, 1988b; with a diameter of 12 kpc) is also weaker than the LMC.

The integrated spectra of the LMC and SMC are very similar; the SMC spectrum is somewhat steeper between 60 and 25  $\mu\text{m}$ . The spectra are characteristic of warm dust clouds associated with HII regions; they resemble the infrared spectrum of the active irregular galaxy NGC 4449 and are clearly warmer than most Local Group spiral galaxies. The peak in the Clouds' spectra is closer to 100  $\mu\text{m}$  than in the spectra of M31 or diffuse Galactic emission (which have cool dust spectra  $T_d \approx 25 \text{ K}$  peaking well beyond 100  $\mu\text{m}$ ); the dust in both Clouds has a high average temperature (33 K). The spectral difference at the 12  $\mu\text{m}$  side of the spectrum shows that the 12  $\mu\text{m}$  excess is less pronounced in the Clouds ( $T_{12-25\mu\text{m}} \approx 240 \text{ K}$ ) than in M31 and typical cirrus areas in our Galaxy, where  $T_{12-25\mu\text{m}} \approx 320 - 380 \text{ K}$  (Walterbos and Schwering, 1987; and Boulanger *et al.*, 1985).

Using the Kuiper Airborne Observatory, Werner *et al.* (1978) observed a flux density of 2000 Jy for 30 Doradus at 200  $\mu\text{m}$ , i.e. 40 % of their 100  $\mu\text{m}$  flux density. Using the average temperature of 33 K and a  $\lambda^{-1.5}$  dust emissivity we estimate the 200  $\mu\text{m}$  integrated flux densities of the Clouds to be about 50 % of the 100  $\mu\text{m}$  flux densities, hence  $1 \times 10^5 \text{ Jy}$  for the LMC and  $7 \times 10^3 \text{ Jy}$  for the SMC. This is valid if the 33 K component still dominates all the other components at 200  $\mu\text{m}$ , hence if cold dust is not present in large amounts.

**Figure 5.** Integrated infrared spectra of the Magellanic Clouds.

The spectra of the LMC and the SMC are shown by solid lines. Note that the LMC is about 12 times more luminous than the SMC. The spectra of M31 (Walterbos and Schwering, 1987; dashed) and NGC 4449 (Hunter *et al.*, 1986; dotted) are scaled to the distance of the LMC.

### 3.2. Infrared sizes

Rough estimates for the infrared size of the Magellanic Clouds were obtained from the summing method used to determine the integrated flux densities (see Section 3.1 and Fig. 3 and 4). The diameter derived from IRAS AO, Skyflux and Spline-I data for the LMC is  $7^\circ - 8^\circ$  and for the SMC about  $2^\circ - 3^\circ$  at 12 and 25  $\mu\text{m}$  and  $2.5^\circ - 4^\circ$  at 60 and 100  $\mu\text{m}$ . The LMC size obtained from the ZOHF data is  $8^\circ - 8.6^\circ$ .

We now derive a more accurate value for the Clouds' sizes in the infrared. Similar to the definition of the size for galaxies in the optical (de Vaucouleurs *et al.*, 1976: 25

$\text{mag}/(")^2$ , which corresponds to  $0.019 \text{ MJy/sr}$  in the blue) we may define the size by the area with intensity above a certain fixed in-band intensity level of  $2.5 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ , which is about 2 – 5 times the effective noise in the maps. This level corresponds to 0.19, 0.48, 0.97 and  $2.5 \text{ MJy/sr}$  at the 12, 25, 60 and  $100 \mu\text{m}$  bands (10 – 130 times higher than the visual B-limit of de Vaucouleurs). The values for the defined size are dependent on the sensitivity of the IRAS Survey instrument, its resolution and the surface brightness of the Clouds. The surface area of the Clouds with in-band intensities higher than the cut-off values equals an equivalent circular area  $a_{eq}$  with diameter  $d_{eq}$ ; both are given in Table 4. Note that the equivalent diameter assumes a circular aperture for the source, while the equivalent area is independent of the shape of the object. The infrared size differs in the four wavelength bands and is largest in the 60 and  $100 \mu\text{m}$  bands. The sizes are smallest at  $25 \mu\text{m}$ . The 12 and  $25 \mu\text{m}$  sizes are 0.4 – 0.8 times the 60 and  $100 \mu\text{m}$  sizes. The equivalent diameter is smaller than the first estimates presented in this section; caused by the presence of areas below the intensity cut-off.

Similar sizes in all four bands are obtained by adopting different intensity cut-off levels for the individual bands, *e.g.* by lowering the intensity cut-off at  $25 \mu\text{m}$  to  $0.5 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$  and to  $1.3 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$  at  $12 \mu\text{m}$ , about equal to the noise levels in these bands. These cut-off values are unrealistically low, and the size may now be strongly influenced by the statistical properties of noise in the maps. We can also increase the 60 and  $100 \mu\text{m}$  cut-off limits to about  $10 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ , resulting in a similar size in all four infrared bands.

The Clouds' size in blue light (de Vaucouleurs *et al.*, 1976; Table 3) is roughly twice the infrared (60 and  $100 \mu\text{m}$ ) size. Deep visual photographic images of West *et al.* (1987) show a halo extending over  $11^\circ \times 15^\circ$  (*i.e.* a linear scale of  $11 \times 15 \text{ kpc}$ ). The infrared images show a size that corresponds to red isophotes of de Vaucouleurs (1957) of  $0.06 \text{ MJy/sr}$  for both Clouds, but for the SMC-Wing of about  $0.03 \text{ MJy/sr}$ . Also in red light much lower Cloud intensity levels are visible. The smaller infrared size is mainly the result of a higher sensitivity at visual wavelengths compared to infrared wavelengths.

### 3.3. Luminosities and luminosity ratios

The infrared luminosity of the Magellanic Clouds can be determined in different ways. In Table 4, we first give the infrared monochromatic luminosities  $L_\nu$  for the 12, 25, 60 and  $100 \mu\text{m}$  bands (these can also be called in-band luminosities, and are integrated over the IRAS bands); this is what has been measured by IRAS. As an estimate for the total infrared luminosity of the Clouds we give four values:

- (1) the sum of the four monochromatic infrared luminosities:  $L_{12+25+60+100\mu\text{m}}$ ;
- (2) the total mid-infrared 'hot'-flux (8 –  $30 \mu\text{m}$ ) luminosity:  $L_{hot}$ ;
- (3) the total far-infrared 'cool'-flux ( $42.5 - 122.5 \mu\text{m}$ ) luminosity:  $L_{cool}$ ;
- (4) the 'hot'-flux (2) and 'cool'-flux (3) components extrapolated from 1 –  $500 \mu\text{m}$  and combined:  $L_{hot'}$ ,  $L_{cool'}$ ,  $L_{tot}$ .

Method (4) extrapolates the 60 –  $100 \mu\text{m}$  spectra over the infrared from 1 –  $500 \mu\text{m}$  using an emissivity  $\epsilon_\nu \propto \nu^{1.5}$  and a 33 K grain temperature (based on  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$ ). We used a similar method as IRAS (1985c): a factor of 1.26 to fill in the 60 –  $100 \mu\text{m}$  wavelength band gap and a factor of 1.35 to extrapolate beyond  $100 \mu\text{m}$  follows from the observed dust temperature. This results in an integrated infrared 'cool-dust' luminosity  $L_{cool'}$  for

the LMC of  $7.1 \times 10^8 L_\odot$  and for the SMC of  $6.8 \times 10^7 L_\odot$ . By extrapolating the 12 – 25  $\mu\text{m}$  spectra (240 K) over the whole infrared 1 – 500  $\mu\text{m}$  assuming a blackbody emission curve we found the 'hot-dust' luminosities  $L_{\text{hot}'}$  to be  $1.8 \times 10^8 L_\odot$  (20 % of the total integrated luminosity) for the LMC and  $8.1 \times 10^6 L_\odot$  (11 % of the total) for the SMC. The two extrapolated luminosities sample different temperature regimes. The 240 K blackbody, discussed in Section 4.2, emits 10 times more in the 8 – 30  $\mu\text{m}$  range than in the 42.5 – 122.5  $\mu\text{m}$  wavelength range; while for the 44 K blackbody this ratio is 0.008. Because we have observed a ratio of "hot-flux"/"cool-flux" of only 0.1 – 0.3, i.e. very different from either two, we can add these integrated components yielding total infrared luminosities  $L_{\text{tot}} \equiv L_{\text{hot}'} + L_{\text{cool}'}$  of  $9 \times 10^8 L_\odot$  for the LMC and  $8 \times 10^7 L_\odot$  for the SMC.

Table 4 also contains luminosities at other ( $\text{H}\alpha$ ,  $\text{Ly}\alpha$ , V, B, UV) wavelengths and ratios of  $L_{\text{cool}}$  with these data (Table 4 contains their definitions). The LMC value of  $L_{\text{cool}}/L_B$  is about 1.7 times higher than the SMC value, which in turn is about two times higher than the value for M31 (see Caspers, 1987). Thus, the importance of dust emission relative to stellar emission increases from M31 to the SMC, to the LMC; M33 is inbetween the two Clouds. This illustrates the relative increases in dust content. The ratio of  $L_{\text{cool}}/L_{\text{H}\alpha}$  is much less than the other ratios due to the fact that  $\text{H}\alpha$  is line emission and fills only a small wavelength band (equivalent width  $W_\lambda = 35 \text{ \AA}$ ). The ratio is 2.8 times higher for the LMC than for the SMC. From the  $\text{H}\alpha$  emission we have derived the equilibrium  $\text{L}\alpha$  emission for a HII region ( $10^4 \text{ K}$  hydrogen gas).

We have calculated the stellar emission from two components. The spectral shapes of the visual data between 4400 and 6250  $\text{\AA}$  of de Vaucouleurs (1960) give both Clouds an average F5 (6700 K) spectrum. We compared the absolute magnitudes of the Clouds ( $V_{\text{LMC}} = -18.5 \text{ mag}$ ,  $V_{\text{SMC}} = -16.8 \text{ mag}$ ) with the F5 absolute magnitude ( $V_{F5} = 3.6 \text{ mag}$ ) and then integrated the F5 spectrum over all wavelengths. The magnitudes correspond to  $6.9 \times 10^8$  F5-type stars for the LMC and  $1.5 \times 10^8$  for the SMC. Each F5 dwarf has a luminosity of  $2.5 L_\odot$  (Mihalas and Binney, 1981, p114), and hence we obtain  $L_{F5} = 1.7 \times 10^9 L_\odot$  and  $3.6 \times 10^8 L_\odot$  for the LMC and SMC resp. The ultraviolet 1690  $\text{\AA}$  data of Lequeux (1984) were used to determine the luminosity of hot stars. We assume a B0 spectrum (Mihalas and Binney, 1981) and derive a number of about 9000 of these stars in the LMC and about 2500 in the SMC. This results in a luminosity of  $L_{B0} = 5.8 \times 10^9 L_\odot$  for the LMC and  $1.6 \times 10^8 L_\odot$  for the SMC (equal amounts of B0 main sequence stars and supergiants are assumed). The total stellar luminosity is the sum of the two components and is given in Table 4. The luminosities are correct within a factor of 2 due to extinction effects. We derive  $L_{\text{cool}}/L_{\text{stellar}} = 0.23$  and 0.10 for the LMC and SMC. In principle, all infrared radiation comes from stars; but 23 % of the stellar radiation of the LMC is re-emitted in the infrared and only 10 % in the SMC. This shows the relative weak conversion of starlight into infrared radiation by the SMC compared to the LMC, which can be caused by a low dust content.

The ratio of total infrared luminosity to gas mass for the LMC and SMC are 1.3 and 0.12 times the Solar Neighbourhood value of  $1 L_\odot/M_\odot$  (Boulanger and Perault, 1987). At 1690  $\text{\AA}$ , Lequeux (1984) has derived (extinction corrected) luminosity-to-mass ratios for the Clouds of 1.3 and 0.30. The LMC ratio corresponds well to our value, but the SMC has a ratio 2.5 times higher than ours. This again shows the relative weakness of the SMC's infrared emission.

Table 4. Derived integrated infrared properties of the Magellanic Clouds.

Property	Unit	LMC	SMC
Equivalent infrared size/diameter <sup>a)</sup> :			
$(I_\nu \Delta\nu > 2.5 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1})$ :			
12 $\mu\text{m}$ ( $I_\nu > 0.19 \text{ MJy/sr}$ )	$(^\circ)^2/^\circ$	$a_{eq} / d_{eq}$ 20.7 / 5.1	$a_{eq} / d_{eq}$ 1.1 / 1.2
25 $\mu\text{m}$ ( $I_\nu > 0.48 \text{ MJy/sr}$ )	$(^\circ)^2/^\circ$	10.8 / 3.7	0.7 / 0.9
60 $\mu\text{m}$ ( $I_\nu > 0.97 \text{ MJy/sr}$ )	$(^\circ)^2/^\circ$	31.2 / 6.3	4.4 / 2.4
100 $\mu\text{m}$ ( $I_\nu > 2.50 \text{ MJy/sr}$ )	$(^\circ)^2/^\circ$	34.0 / 6.6	4.2 / 2.3
Monochromatic infrared luminosities <sup>b)</sup> :

## Notes to Table 4:

- a) The equivalent diameter has been calculated as follows: The area  $a_{eq}$  of the two galaxies of all the pixels that have  $I_{\nu}\Delta\nu > 2.5 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$  was selected and was transferred to a circular area with the same size. Both the area size (square degrees) as well as equivalent diameter  $d_{eq}$  are given. The chosen limit is about 2 times the noise at  $12 \mu m$  and increases in the other bands to 4–5 times the noise at  $100 \mu m$ . At the distance of the LMC  $5^\circ$  corresponds to  $4.5 \text{ kpc}$ ; at the distance of the SMC  $2^\circ$  corresponds to  $2.2 \text{ kpc}$ .
- b) The following luminosities have been calculated via  $L = 4\pi D^2 F$ , using a distance  $D$  of  $53 \text{ kpc}$  for the LMC and  $63 \text{ kpc}$  for the SMC. We have used the true flux densities of Table 3. First of all the "monochromatic" luminosities for each IRAS band individually, for which we used  $F \equiv \Delta\nu f_{\nu}$ , and the sum of these four monochromatic luminosities (with  $F \equiv \sum_{12+25+60+100 \mu m} \Delta\nu f_{\nu}$ ). To obtain luminosities with  $F = \nu f_{\nu}$  the given monochromatic luminosities must be multiplied by 1.85, 2.32, 1.94 and 3.00 at 12, 25, 60 and  $100 \mu m$ . The mid-infrared ( $8 - 30 \mu m$ ) 'hot'-flux has been defined by us as  $F_{hot} \equiv 1.26 (13.48 f_{12 \mu m} + 5.16 f_{25 \mu m}) \times 10^{-14} \text{ Watt m}^{-2}$  similar to the far-infrared ( $42.5 - 122.5 \mu m$ ) 'cool'-flux (see IRAS 1985c:  $F_{cool} \equiv 1.26 (2.58 f_{60 \mu m} + 1.00 f_{100 \mu m}) \times 10^{-14} \text{ Watt m}^{-2}$ ). Both of these have been transformed to luminosities:  $L_{hot}$ ,  $L_{cool}$ . The integrated 'hot'-flux' has been defined by extrapolating the ( $8 - 30 \mu m$ ) 'hot'-flux over the infrared range  $1 - 500 \mu m$  using the appropriate  $240 \text{ K}$  colour temperature (multiplication by a factor 1.31):  $L_{hot'}$ . The integrated 'cool'-flux has been defined in the same way ( $33 \text{ K}$ ; multiplication by a factor of 1.35):  $L_{cool'}$ .  $L_{tot}$  is the sum of the luminosity of these two extrapolated components. The values of  $L_{H\alpha}$ ,  $L_{Ly\alpha}$ ,  $L_V$ ,  $L_B$  and  $L_{UV}$  have been calculated in the same way (integrated over the observed band) from the following data: The  $H\alpha$  luminosities ( $\lambda = 6563 \text{ \AA}$ ,  $\Delta\lambda = 600 \text{ \AA}$ ) were calculated from the uncorrected fluxes ( $F \equiv \int f_{\nu} d\nu$ ) of Kennicutt and Hodge (1986). The luminosity of  $Ly\alpha$  has been calculated from  $L_{H\alpha}$  after applying a multiplication factor of  $j_{Ly\alpha}/j_{H\alpha} = 11.4$  (see Osterbrock, 1974; Table 4.1 therein) for a  $10^4 \text{ K}$  hydrogen gas. The

ratio  $L_{cool}/L_{Ly\alpha}$  is often referred to as the infrared excess IRE. The V ( $\lambda = 5500 \text{ \AA}$ ,  $\Delta\lambda = 0.087 \text{ \AA}$ ) and B ( $\lambda = 4400 \text{ \AA}$ ,  $\Delta\lambda = 0.098 \text{ \AA}$ ) magnitudes are from de Vaucouleurs (1960), they have been converted to luminosities using the recipe of Zombeck (1980). The ultraviolet (UV:  $\lambda = 1690 \text{ \AA}$ ,  $\Delta\lambda = 330 \text{ \AA}$ ) is taken from Lequeux (1984). The F5 stellar luminosity has been calculated by comparing the V with the average Clouds' spectra (F5) and extrapolating the F5-spectrum in solar luminosity; the B0 luminosity from comparison of ultraviolet data. The stellar luminosity is the sum of these two components.

- c) These ratios are calculated for the 'cool' dust luminosity. The ratios with  $L_{hot}$  are 3.8 times smaller for the LMC and 8.1 times for the SMC; the ratios with  $L_{tot}$  are 1.7 and 1.5 times larger resp.
- d) The infrared luminosity-to-gas mass ratio has been obtained from the value of  $L_{tot}$  and the HI masses ( $5.4$  and  $4.8 \times 10^8 M_{\odot}$ ) corrected for He by multiplying with 1.3 (see Lequeux, 1984). The gas masses for both Clouds are very similar. The values  $L_{tot}/M_{tot}$  are 0.15 for the LMC and 0.05 for the SMC (with total dynamic masses of 6 and  $1.5 \times 10^9 M_{\odot}$ ).
- e) The average dust temperatures have been calculated assuming blackbody emission and  $\epsilon_{\lambda} \propto \lambda^{-n}$ . For  $n = 0$  colour-temperatures are obtained (indicated by an index -), and for  $n > 0$  dust temperatures are obtained by assuming an emissivity with the given value of  $n$  (indicated by an index /).

Table 5. Comparison with other galaxies.

Galaxy	Distance (kpc)	Diameter (kpc)	Total infrared ( $L_{\odot}$ )	$\frac{LMC}{galaxy}$ (%)	$\frac{SMC}{galaxy}$ (%)	$\frac{12+25\mu m}{60+100\mu m}$ (%)	a) Reference
LMC	53	7.8	$8.9 \times 10^8$	100.	8.7	26	This chapter.
SMC	63	2.6	$7.7 \times 10^7$	1160.	100.	12	This chapter.
MWG 1 <sup>b)</sup>	—	50	$1.5 \times 10^{10}$	6.	0.5	24	Cox <i>et al.</i> (1986).
MWG 2	—	50	$8.6 \times 10^9$	10.	0.9	50	Cox and Mezger (1988).
M31	690	60	$2.6 \times 10^9$	34.	3.0	70	Walterbos and Schwering (1987).
M33	660	12	$1.1 \times 10^9$	81.	7.0	33	Rice <i>et al.</i> (1988).
NGC 4449 <sup>c)</sup>	5400	9.4	$5.8 \times 10^9$	15.	1.3	32	Hunter <i>et al.</i> (1986).

Notes to Table 5:

a) The ratio  $\frac{12+25\mu m}{60+100\mu m}$  is defined as:  $\frac{\Delta\nu_{12\mu m} f_{12\mu m} + \Delta\nu_{25\mu m} f_{25\mu m}}{\Delta\nu_{60\mu m} f_{60\mu m} + \Delta\nu_{100\mu m} f_{100\mu m}}$ .

b) For the Milky Way Galaxy, two references are used: MWG 1 is based on pre-IRAS data of Cox *et al.* (1986), and MWG 2 is based on post-IRAS data of Cox and Mezger (1988). The luminosity ratio  $\frac{12+25\mu m}{60+100\mu m}$  calculated as (hot dust)/(warm + cold + very cold dust) of Cox *et al.* gives 15 %.

c) Note that the total infrared luminosity of NGC 4449 is 3 times higher than given by Hunter *et al.* as a result of the different definitions of the quantity.

Infrared luminosities for other Local Group galaxies are given by Walterbos and Schwing (1987) on M31, Rice *et al.* (1988b) on M33 and by Cox *et al.* (1986) for the Milky Way galaxy. The active giant irregular galaxy NGC 4449, which is a reasonably well studied galaxy with similar infrared properties as the Clouds, has been described by Hunter *et al.* (1986). The values of the Magellanic Clouds and these other galaxies are listed in Table 5. The fact that the Clouds and the Galaxy have higher star formation rates per unit total mass than M31 and M33, indicates that the 'hot'-flux component is not related to star formation. Although the star formation rate of the SMC is smaller than that of the LMC, the 'hot'-flux component is also smaller. Hence there is not a perfect anti-correlation. The Clouds have lower 12 and 25  $\mu\text{m}$  emission relative to 60 and 100  $\mu\text{m}$  than the other galaxies.

## 4. Large scale infrared structure of the Magellanic Clouds

### 4.1. Infrared morphology

In this section we examine the large scale infrared structure of the Magellanic Clouds. The IRAS Additional Observation (AO) maps, centered on the Clouds and convolved to a resolution of 8' are shown in Fig. 1 and 2. Grey scales emphasize lower emission levels. In general the infrared maps resemble the optical image of the Magellanic Clouds. We see diffuse infrared emission in both Clouds, especially at 60 and 100  $\mu\text{m}$ , that extends beyond obvious active star formation regions. This is less the case in the 12 and 25  $\mu\text{m}$  bands, where the extended emission is less bright. There is a wide range in infrared intensity values in all four bands. For each Cloud, the infrared maps at different wavelengths are very similar in appearance: they show the same low level diffuse emission and similar peaks at the HII regions. This indicates that at a scale of 8' the mechanism responsible for the infrared radiation in each of the four IRAS bands has the same spatial distribution. Relatively small differences between the infrared wavelength maps result from different colour-temperatures (*e.g.* stars -  $T \sim 3000$  K). The main infrared components in normal galaxies are dust associated with HII regions, heated to high temperatures (30 - 50 K) and dust heated by the interstellar radiation field to temperatures of 20 - 25 K, mixed with the neutral HI gas. In the Milky Way galaxy Cox *et al.* (1986) have estimated that roughly 50 % of the infrared radiation comes from either component. Recently a third component is introduced, Polycyclic Aromatic Hydrocarbons (PAHs; Puget *et al.*, 1985) to explain the relatively strong IRAS 12 and 25  $\mu\text{m}$  emission; these grains are also well mixed with the HI distribution (see Chapter VI).

We have calculated the contribution to the integrated infrared flux densities from unresolved sources from the infrared source lists from Chapters II and III (see Table 3). The point sources were found on the full resolution AO maps which have a much higher resolution at the 12 and 25  $\mu\text{m}$  bands and a somewhat higher resolution at 60  $\mu\text{m}$  compared to 100  $\mu\text{m}$ . At higher resolutions unresolved sources are more easily recognized (less confusion with other sources and with backgrounds), hence at 12 and 25  $\mu\text{m}$  we expect a larger number of point sources. The significantly higher point source contribution at 25  $\mu\text{m}$ , is an indication that this band is more dominated by point sources than the other bands. The explanation is most likely a minimum in the diffuse extended emission at 25

$\mu\text{m}$ . At 60 and 100  $\mu\text{m}$  the cool-dust component dominates and has a spectrum increasing with wavelength, while the hot-dust component related to the diffuse infrared emission has a spectrum decreasing with wavelength. For the LMC the relative point source component at 12  $\mu\text{m}$  equals that of 60 and 100  $\mu\text{m}$ ; in the SMC it is a factor of 2 higher. The point source contribution in the SMC is higher than in the LMC, indicating that the infrared emission of the SMC is more dominated by point sources than that of the LMC. The ratio of the flux densities of the point sources in the LMC and of that in the SMC is constant ( $\sim 12$ ) in all four bands.

Notes to Table 6 and 7:

- The areas given in these tables are defined by masking the visual areas. The Greater Doradus Region contains some weak infrared emission at the East side. The LMC Rest-area is the total LMC minus the Bar, Constellation III, the Greater Doradus Region and the area South of the Doradus Region. 30 Doradus is a part of the Greater Doradus Region. N 66 is a part of the SMC NE-Bar.
- The flux densities  $f_\nu$  have been obtained by summing intensities in the defined areas and correcting for a planar background.
- The surface brightness  $\sigma_\nu$  is obtained by dividing the integrated flux density in each area by the equivalent area.
- Colour temperatures ( $T_{\nu_1-\nu_2}$  assuming  $\epsilon_\nu$  to be independent of frequency) have been derived from the integrated flux densities in the areas.

For a discussion of the LMC and its young stellar constituent, in particular the 30 Doradus region we refer to Feitzinger (1980). The infrared emission follows the large-scale filaments of star formation as described in Feitzinger *et al.* (1988). The LMC 12 and 25  $\mu\text{m}$  maps show some bright (stronger than 3 Jy) Galactic foreground stars (SAO 249123; SAO 249138; SAO 249225, RX-Dor, LI-LMC 324 and LI-LMC 1623). The 60 and 100  $\mu\text{m}$  bands of the LMC show Galactic emission in the SW edge (which unfortunately has a spectrum similar to that of cool LMC dust). Prominent objects in the four LMC infrared maps are the Bar and the Greater 30 Doradus region. Another HII region that shows up clearly is N 11 in the NW corner. The area surrounding Constellation III is a weak infrared emitting area and therefore Constellation III itself can be distinguished very well. At the LMC's South side a sharp edge can be seen East of the 30 Doradus region. Also in other wavelength regions (*e.g.* HI observations of Mathewson and Ford, 1984) sharp edges are seen there. Here no low level emission areas are present in any of the four wavelength bands. The integrated properties of some selected areas of the LMC are given in Table 6. The Greater 30 Doradus region contains about 30 – 40 % of the total emission, somewhat more at 25  $\mu\text{m}$  (50 %), while it contains only 10 % of the total LMC surface area. The area called Rest in Table 6, which contains the 66 % of the LMC surface not already in the other areas, is less bright at 25, 60 and 100  $\mu\text{m}$  and has a similar brightness as the Greater Doradus region at 12  $\mu\text{m}$ . The surface brightness is highest for the Greater 30 Doradus region, it is about nine times brighter than Rest. The Bar region is four times, and the region Constellation III is two times brighter than the Rest region. The area South of the 30 Doradus region is 2 times brighter than Rest at 12 and 25  $\mu\text{m}$  and equally at 60 and 100  $\mu\text{m}$  as Rest. Thus the region South has an infrared spectrum that resembles the diffuse emission (and Galactic cirrus) spectrum. The spectrum of the Rest region resembles the integrated infrared spectrum of the LMC.

In the SMC infrared maps we distinguish the Bar and the Wing; at 60 and 100  $\mu\text{m}$  Bar and Wing are connected by diffuse emission. In the SMC the Bar and its HII regions N 66, N 76 and N 78 show up prominently in the infrared. A foreground star (LI-SMC 186) is seen at 12  $\mu\text{m}$  between the Bar and the Wing with 2.6 Jy (see also Section 4.2). The SW part of the Bar has a very long line-of-sight (Mathewson *et al.*, 1986; van Genderen, 1981) and the observed peak in the infrared emission is therefore not completely unexpected. It may be produced by the combined effect of the larger column of dust in this direction, and the wider spread in line-of-sight temperatures, resulting in a higher average  $T_d$ . The HII regions in the Shapley Wing of the SMC are also prominent infrared emitting objects (especially N 83/84). Integrated properties for some individual areas are given in Table 7. The SMC-Wing is clearly weaker than the Bar in the infrared. The surface brightness in the SW-Bar is about 1.5 times that in the NE-Bar (2 times higher at 12  $\mu\text{m}$ ). The surface brightness in the NE-Bar is identical to that in the Wing at 12 and 25  $\mu\text{m}$ , but two times higher at 60 and 100  $\mu\text{m}$ . In the average temperatures we see no clear differences between the three regions.

#### 4.2. Line-of-sight temperature distribution of the dust

Using the spectral response of the photometric bands (IRAS Explanatory Supplement, IRAS 1985a; Table II.C.5 therein) we have calculated tables with theoretical in-band fluxes ( $\text{Watt m}^{-2} \text{sr}^{-1}$ ), flux densities (MJy/sr) and in-band ratios for a fixed amount of dust of

temperature  $T_d$  (K) at a fixed distance. To calculate theoretical in-band fluxes and ratios we have assumed equilibrium blackbody radiation from the dust grains and an emissivity  $\epsilon_\nu \propto \nu^{1.5}$  (for a complete discussion see the Appendix). We call this temperature, dust temperature, because we have used an emissivity.

From the band ratios of 60 and 100  $\mu\text{m}$  we calculate the average temperature  $T_d$  of the dust along the line-of-sight, yielding the distribution of  $T_d$  over the face of the Clouds (Fig. 6). Intensity cut-offs have been applied in both bands at about three times the noise level to avoid noise blow up.

We see significant temperature variations over the face of the Clouds. From Fig. 6 we see three main dust temperature regimes:

- (1) a low level extended regime with a temperature of about 22 – 28 K. This regime, which is related to the diffuse emission, is present especially at the edges of the LMC, where no HII regions are found. This regime contains 20 % of the LMC area with 11 % of the total flux; its size is negligible for the SMC. Its origin is probably dust heated by the general interstellar radiation field. Its detection in the central parts of the Clouds is hampered by the presence of warmer dust in the lines-of-sight (regimes 2 and 3).
- (2) an intermediate, extended regime of about 28 – 32 K around the warm HII regions. Basically this regime is associated with HII regions, but is much more extended; also the LMC and SMC bars show up. This regime contains 68 % of the LMC area with 52 % of the total flux and 45 % of the SMC area with 23 % of the flux. Note that this regime is more difficult to separate from regime 3 in much farther galaxies due to the lower spatial resolution (see *e.g.* Walterbos and Schwing, 1987). Its origin is, first of all, a mixture of warm (regime 3) and cool dust (regime 1) in the line-of-sight and dust heated by the average Cloud radiation fields.
- (3) warm infrared sources associated with HII regions (32 – 45 K, like *e.g.* 30 Doradus in the LMC). This regime contains only discrete objects, with the exception of the Greater 30 Doradus region. This regime contains 12 % of the LMC area with 37 % of the total flux and 55 % of the SMC area with 77 % of the total flux. The emission comes from dust in and close to HII regions.

In the LMC area South of 30 Doradus we find, in order, the HII regions N 158, N 160 and N 159 (Henize, 1956). Here, the line-of-sight temperature remains above 35 K. In the LMC-Bar the temperature is about 30 – 35 K, peaking in HII regions to values above 35 K and in N 11 37 K. The high stellar density in the Bar is the origin for this higher temperature. Around Shapley's Constellation III the temperature is also higher than in the global component (31 K). This constellation shows only weak infrared intensities and is known to have many stellar associations (Lucke and Hodge, 1970).

The dust temperature in the SMC (Fig. 6.2) ranges from 28 to 43 K. The average temperature regime in the Bar of the SMC is about 32 – 34 K. The dust temperature peaks just above 37 K in the HII regions N 66, N 76 and N 78, and in the HII regions in the Shapley wing N 81, N 83 and N 84; the compact nebula N 88 is the hottest with a peak temperature above 43 K. Between the Bar and the Wing the temperature is lowest, about 28 – 30 K; this area resembles a Galactic cirrus area. In the main body of the SMC there is only a small area with diffuse emission. In the SMC-Bar the high stellar density produces a strong radiation field which in its turn heats up the dust grains in the Bar to higher temperatures.

**Figure 6.** Line-of-sight dust temperature distribution in the Magellanic Clouds deduced from the infrared maps at 60 and 100  $\mu\text{m}$  at a resolution of 8' and assuming a dust emissivity with a  $\lambda^{-1.5}$  wavelength dependence. Intensity cut-offs at  $2.5 \times 10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$  have been applied to avoid noise blow-up.

**Fig. 6.1.** Dust temperature map of the LMC. Darker grey scales indicate higher dust grain temperatures (22 – 43 K). Contours are at 25, 30, 35, 40 K.

**Fig. 6.2.** Dust temperature map of the SMC. Darker grey scales indicate higher dust grain temperatures (28 – 43 K). Contours are at 30, 35, 40 K.

Fig. 7.1 to 7.4 show the colour temperature distribution obtained from the 12 to 25  $\mu\text{m}$  and from the 25 to 60  $\mu\text{m}$  intensities for both Clouds. Colour temperatures are defined as the blackbody temperature that has the same intensity ratio between two frequencies as the observed ratio (because the emissivity is somewhat uncertain in this wavelength range we did not adopt an emissivity). The LMC maps have the following characteristics. The 12 – 25  $\mu\text{m}$  colour temperature has a global hot component higher than 300 K; minima of 150 – 260 K occur in the HII regions like 30 Doradus and the maximum of about 350 K occurs in the area South of the Greater 30 Doradus region (this area is quite similar to Galactic cirrus). Three foreground stars, SAO 249225, LI-LMC 1623 and LI-LMC 324 (RX-Dor) peak at values of 800 K (lower than normal for stars due to beam dilution). For the 25 – 60  $\mu\text{m}$  colour temperature we have a global component of 60 – 67 K over a large part of the LMC. HII regions peak at 70 – 90 K and in the region South of the Greater 30 Doradus region peaks are at 70 – 80 K. The maxima in these maps have a temperature of about 120 K and coincide with infrared sources LI-LMC 181 and 1100 (both W-type spectra, characteristic of hot dust shells; see Chapter III). Note that LI-LMC 181 was described by Elias *et al.* (1986) as a candidate OH/IR star. Their other candidate, LI-LMC 1341, also shows a peak in the 25 – 60  $\mu\text{m}$  colour temperature map, just SW of N 160 in the Greater 30 Doradus region. A summary of line-of-sight temperatures is given in Table 8.

The characteristics of the SMC are as follows. In the 12 – 25  $\mu\text{m}$  colour temperature map we see the SW-Bar (with a long line of sight and a high infrared intensity) with 150 – 200 K, maxima of about 200 – 280 K (at the edges some noise blow-up occurs due to the low-level 25  $\mu\text{m}$  emission), while the HII regions again are coolest with 150 – 200 K. One foreground star, LI-SMC 186 shows up 800 K. The 25 – 60  $\mu\text{m}$  colour temperature shows HII regions at 65 – 80 K and minima of about 58 – 66 K. Just North of the SW-Bar in the SMC at  $\alpha = 00^{\text{h}}47^{\text{m}}$ ,  $\delta = -73^{\circ}07'$  we see a high dust temperature together with almost a minimum in the 25 – 60  $\mu\text{m}$  colour temperature (at least much lower than normal HII regions). At this position the intensity drops very rapidly with decreasing wavelength. The SMC shows some 25 – 60  $\mu\text{m}$  temperature peaks. A summary of characteristic line-of-sight temperatures is given in Table 9.

The Clouds average colour temperatures increase toward shorter wavelengths ( $\partial T/\partial \lambda < 0$ ). This shows that the radiation at 12 and 25  $\mu\text{m}$  is in excess over the cool dust emission (with  $T_d \sim 33$  K) that is responsible for the infrared emission at 60 and 100  $\mu\text{m}$ . For M31 Walterbos and Schwing (1987) found much more extreme values for the temperatures ( $T_{60-100\mu\text{m}} = 24$  K, for  $n = 1.5$ ; and  $T_{12-25\mu\text{m}} = 380$  K) than we find for the Clouds. The diffuse emission areas in the Clouds have more similar temperature characteristics as M31.

**Figure 7.** Line-of-sight colour temperature in the Magellanic Clouds deduced from the infrared maps at 12 and 25  $\mu\text{m}$  and from the maps at 25 and 60  $\mu\text{m}$  at a resolution of  $8'$  (i.e. blackbody emission is assumed). In the LMC maps cut-offs have been applied at  $1.5 \times 10^{-8}$  Watt  $\text{m}^{-2}$   $\text{sr}^{-1}$ , and in the SMC of  $0.5 \times 10^{-8}$  Watt  $\text{m}^{-2}$   $\text{sr}^{-1}$ . See pages 174 – 175.

Table 8. Dust temperatures for different areas in the LMC. <sup>a)</sup>

Object/Region Assumed emissivity	Area (%)	$T_{12-25\mu m}$ (K) ( $\epsilon_\nu \propto \nu^0$ )	$T_{25-60\mu m}$ (K) ( $\epsilon_\nu \propto \nu^0$ )	$T_{60-100\mu m}$ (K) ( $\epsilon_\nu \propto \nu^{1.5}$ )
HII regions	6	150 – 240	70 – 90	32 – 45
Intermediate component (around HII regions)	14	240 – 300	60 – 67	28 – 32
Diffuse emission	9	>300	70 – 80	22 – 28
LMC-Bar	14	240 – 280	67 – 74	30 – 35
LMC-Average	10	240 – 260	70 – 76	30 – 34

Table 9. Dust temperatures for different areas in the SMC. <sup>a)</sup>

Object/Region Assumed emissivity	Area (%)	$T_{12-25\mu m}$ (K) ( $\epsilon_\nu \propto \nu^0$ )	$T_{25-60\mu m}$ (K) ( $\epsilon_\nu \propto \nu^0$ )	$T_{60-100\mu m}$ (K) ( $\epsilon_\nu \propto \nu^{1.5}$ )
HII regions	2	140 – 180	65 – 80	34 – 43
Intermediate component (around HII regions)	7	170 – 200	55 – 65	31 – 34
Diffuse emission	2	–	–	28 – 31
SMC-Bar	5	170 – 200	55 – 65	32 – 34
SMC-Average	8	220 – 240	60 – 66	31 – 35

Note to Tables 8 and 9:

- a) The area that is characteristic for each component is given; hence the sum is less than 100 %.

Comparing the temperature distribution  $T_{60-100\mu\text{m}}$  (Fig. 6) with the infrared intensity  $I_{60\mu\text{m}}$  distribution (Fig. 1) we see that on scales of 135 pc (8' resolution) the temperature distribution correlates well with the infrared intensity (an exception is Constellation III with a higher  $T_d$  and a relatively low infrared intensity). For thermal infrared emission we expect the intensity to go with a high power of the temperature ( $I_\nu \propto T^{4+n}$ ) so that a correlation is to be expected. The effect is particularly visible in pixel-to-pixel scatter diagrams (see Fig. 8). At high values of  $I_{100\mu\text{m}}$  the slope  $I_{100\mu\text{m}}/I_{60\mu\text{m}}$  decreases, showing that higher intensities are related to higher temperatures. At  $I_{100\mu\text{m}} = 20 - 30 \text{ MJy/sr}$ , the LMC diagram shows a clear change in slope. A large fraction of the infrared radiation has high dust temperatures and is related to the intermediate and warm temperature components.

At higher intensities (*i.e.* in and near HII regions) the 25/60  $\mu\text{m}$  ratio map correlates well with infrared intensity. Discrepancies appear at lower intensity values (along the edges of the SMC-Bar; South of 30 Doradus in the LMC). In fact, at lower intensities there appears to be an anti-correlation between the 25 - 60  $\mu\text{m}$  colour temperature and intensity. The 12 - 25  $\mu\text{m}$  colour temperature distributions anti-correlate with infrared intensity at all intensity levels. This effect (already noticed on much larger scales in M31 by Walterbos and Schwing, 1987; in the Galaxy by Boulanger *et al.*, 1985; Boulanger *et al.*, 1988) is seen in the SMC maps and is more clearly present in the LMC maps. Therefore, we expect an anti-correlation of  $I_{12\mu\text{m}}/I_{25\mu\text{m}}$  and  $I_{60\mu\text{m}}/I_{100\mu\text{m}}$ ; hence also between  $T_{12-25\mu\text{m}}$  and  $T_{60-100\mu\text{m}}$ . This expectation is confirmed by Fig. 9, which shows three types of colour-colour pixel-to-pixel scatter diagrams of the band ratios, in the same way as Helou (1986) did for integrated flux densities of a large sample of unresolved galaxies. Cut-offs in intensity were applied at 3 - 5 times the noise level to reduce noise blow-up effects. We find a similar relation as Helou, somewhat below his curve marked H. The importance of this diagram is that it connects the infrared structure of the Clouds to the integrated properties of the galaxies studied by Helou. The SMC diagram shows a lesser amount of cool 60 and 100  $\mu\text{m}$  emission.

For HII regions the ratio  $I_{25\mu\text{m}}/I_{60\mu\text{m}}$  correlates with  $I_{60\mu\text{m}}/I_{100\mu\text{m}}$ ; for diffuse emission regions it correlates with  $I_{12\mu\text{m}}/I_{25\mu\text{m}}$ . We have already seen that the two ratios  $I_{12\mu\text{m}}/I_{25\mu\text{m}}$  and  $I_{60\mu\text{m}}/I_{100\mu\text{m}}$  anti-correlate. Thus in areas with low  $I_{25\mu\text{m}}/I_{60\mu\text{m}}$  we do not expect to find typical diffuse areas nor HII regions, but merely the intermediate temperature regime (2). For the California Nebula, Boulanger *et al.* (1988) showed the colour temperatures as a function of the distance from the star. From their profiles we see the same effect: if  $f_{25\mu\text{m}}/f_{60\mu\text{m}}$  is low neither  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  nor  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  are high. For the diffuse regions, the fact that  $T_{60-100\mu\text{m}}$  correlates with  $T_{12-25\mu\text{m}}$  suggests the possibility that very small grains (Puget *et al.*, 1985) contribute to the emission at 60  $\mu\text{m}$ . In Chapter VI we find that 17 % (LMC) and 8 % (SMC) of the integrated 60  $\mu\text{m}$  emission can come from small grains.

With a beam size of 8' we observe an overall correlation between infrared intensity  $I_\nu$  and dust temperature  $T_d$ . On smaller scales a breakdown of this correlation might be possible. Indeed Werner *et al.* (1978) observed the 30 Doradus region at wavelengths of 30, 50, 100 and 200  $\mu\text{m}$  with a smaller beam size (1' = 15 pc). They find that the temperature peak is anti-correlated with infrared intensity. Their resolution is about 8 times better than what we use here and the correlation that we found therefore seems to

**Figure 8.** Pixel-to-pixel scatter diagrams of adjacent IRAS bands for the Magellanic Clouds. For the LMC diagrams, pixels of  $6'$  were used; for the SMC diagrams, pixels of  $3'$  were used. Intensity units are in  $10^{-8} \text{ Watt m}^{-2} \text{ sr}^{-1}$ .

**Figure 9.** Colour-colour diagram showing the relation between the intensity band ratios in the Magellanic Clouds; pixel-to-pixel values of  $10 \log (I_{\nu_1}/\text{Jy sr}^{-1})/(I_{\nu_2}/\text{Jy sr}^{-1})$  are shown. The resolution is  $8'$  and the pixel size is  $3' \times 3'$ . The Cirrus (diffuse emission) point and the Active (HII region) point are indicated by C and A. The dashed box gives the position of integrated galaxy data (Helou, 1986).

**Figure 10.** 30 Doradus cross cuts NS and EW in intensity and in temperature. Notice that the temperature values are much smoother than the intensity fall off. Units are in  $10^{-8}$  Watt  $\text{m}^{-2} \text{sr}^{-1}$  for the intensity maps and in K for the temperature maps. In the EW diagrams E is left; in the NS diagrams S is left. The shown field size in all diagrams is  $1^\circ$ .

be good at large scales but is an oversimplification at small scales of 15 pc. Jones *et al.* (1986), using NASA's KAO at 50 and 100  $\mu\text{m}$  with 40'' (= 10 pc) resolution, observed a mild peaking of temperature (45 K) in N 158 and N 159 on the peak infrared intensities, and this effect showed up even more strongly in the compact HII region N 160A. The HII regions observed by Jones *et al.* are much smaller than 30 Doradus and are not resolved by them. This confirms the above conclusion.

Fig. 10 contains NS and EW crosscuts through the 30 Doradus area. The intensity maps show sharp peaks at 30 Doradus, but the temperature peaks are much broader. This illustrates the much smoother distribution of the dust and colour temperatures compared to the distribution of the infrared emission in this region. It also shows the anti-correlation of the 12 – 25  $\mu\text{m}$  colour temperature with the infrared emission. Note the differences in the NS and EW crosscuts. The NS cuts pass through the active region (with N 158 and N 160 South of 30 Doradus), while the EW cuts only show the 30 Doradus peak.

#### 4.3. Comparison of infrared radiation with H $\alpha$ /HI supergiant shells

The SMC and LMC supergiant shells (SGS) described by Meaburn (1980) show up in the infrared data (see also Chapters II and III). The clearest example of these shells, LMC-SGS 4, is also detected in HI (Rohlfs *et al.*, 1984), and was already noted by Westerlund and Mathewson (1966). In the infrared we clearly detect SMC-SGS 1, and LMC-SGS 1, 2, 4 and 5. All these shells show enhanced infrared emission on top of diffuse infrared emission. The supershells have sizes in the order of 600 – 1400 pc and are not spherical. Their circumferences are places of recent star formation; LMC-SGS 4 contains many HII regions (Davies *et al.*, 1976), OB associations (Lucke and Hodge, 1970) and giant (< 300 pc) shells (Meaburn, 1980). Not all shells are clearly detectable in the infrared; two others are possibly detected, LMC-SGS 3 and 6, and LMC-SGS 9 shows only infrared emission at the East edge. LMC-SGS 7 and 8 are within the complex infrared background of the LMC and cannot be distinguished.

In Fig. 11 we show maps of the relation of the 100  $\mu\text{m}$  infrared intensity, the line-of-sight temperature distribution and dust column density distribution (Chapter VI) of the LMC in grey scales overlayed with the outline-contours of the supergiant shells (Meaburn, 1980). Note the correspondence between the infrared and column density of dust with the supergiant shells, especially LMC-SGS 4. Note the global agreement of dust temperature with the shells. The temperature near the edges of LMC-SGS 4 is clearly higher than in the cool interstellar medium. However, there is no clear tendency for the dust temperature to follow the perimeter exactly; the temperature is higher in a much larger area, inside and outside the shell. Although LMC-SGS 4 is a very bright shell in the infrared, we are not able to recognize it on the basis of the line-of-sight temperature map. This suggests that the higher infrared emission at the perimeter, compared to the inside region, is mainly a dust mass effect. Similar, but less clear, correlations as for LMC-SGS 4 are found for the other shells.

#### 4.4. The density of the Interstellar radiation field

We estimate the density of the interstellar radiation field in the Magellanic Clouds from the line-of-sight dust temperatures  $T_d$ . The energy absorbed each second by a single dust grain,  $W_a = \int_0^\infty 4\pi J_\nu \sigma_\nu d\nu$ , in equilibrium equals the emitted energy per second at

Fig. 11.1.  $I_{100\mu m}$  and SGS outlines.

Fig. 11.2.  $T_d$  and SGS outlines.

Fig. 11.3.  $M_d$  and SGS outlines.

Figure 11. The relation between the LMC's 8' infrared map, the line-of-sight dust temperature map and the dust column density map (all in grey scales) with the supergiant  $H\alpha$  shells (SGS contours) of Meaburn (1980). Lighter grey scales indicate higher levels.

the observed dust temperature,  $W_e = \int_0^\infty 4\pi B_\nu(T_d)\sigma_\nu d\nu$ . We have used the absorption cross-section  $\sigma_\nu$  as given by Cox *et al.* (1986). The average interstellar radiation field we use is a scaled version of the Solar Neighbourhood field:  $J_\nu = \chi J_{\odot;\nu}$  as given by Mathis *et al.* (1983). We calculated an equilibrium temperature for this field of 16 K. From calculations with other absorption cross sections and radiation fields (de Vries, 1986) equilibrium temperatures of  $15 \pm 5$  K are found. Note that the equilibrium temperature of dust in the diffuse interstellar medium is about 25 K (*e.g.* Boulanger and Perault, 1987). From this we obtain the factor  $\chi$ , the ratio of the Clouds local interstellar radiation field and the average Galactic interstellar radiation field. From the temperature maps shown in Fig. 5 we see that the average radiation field in the Clouds must be much stronger than the Solar Neighbourhood field. In view of the large difference between the observed Solar Neighbourhood field and the measured dust temperatures, we normalize the field at a level of 25 K; hence a 10 times higher level. The coolest dust observed in the SMC has temperatures of 27 K, and in the LMC of 22 K; hence those radiation fields will have  $\chi \approx 1$ .

Fig. 12 shows the spatial distribution of the radiation fields (qualitatively these are similar to the dust temperature maps). At the outer edges we find, after the re-normalisation, the lowest values  $\chi \approx 1$ ; peaks occur of  $\chi \approx 10$  in average HII regions, up to 20 in the brightest HII regions as 30 Doradus in the LMC and N 66 and N 88 in the SMC. For the Galaxy van der Kruit (1986) estimates the total disk surface brightness 5 times higher than the local value of  $20 L_{\odot,B}/\text{pc}^2$ . The integrated Clouds temperatures of 33 K leads to a average value of  $\chi \approx 7$ . Hence, the total Galactic value is quite similar to the total Clouds value. Note that we have derived the absorbed part of the ultraviolet radiation field. Due to the influence of the line-of-sight on the dust temperatures the radiation fields may be higher than the average fields in the line-of-sight.

## 5. Comparison of infrared emission with data at other wavelengths

Ultraviolet radiation from OB stars is the most important heating agent for dust. Radiation in the visible also contributes, but much less. Calculations of the absorption of photons in the interstellar radiation field show that more than 95 % of the energy comes from photons with  $900 \text{ \AA} < \lambda < 3000 \text{ \AA}$ . In this section we compare the observed infrared data with three tracers of the OB stellar distribution: (1) the observed ultraviolet radiation gives us this distribution directly; (2)  $\text{H}\alpha$  emission is due to ionisation by OB stars; (3) thermal radio continuum of the ionized medium around OB stars. The last two give indirectly positions of the OB stars. The comparisons of infrared data with ultraviolet and  $\text{H}\alpha$  emission is influenced by sensitivity and extinction.

### 5.1. Comparison of infrared with ultraviolet radiation from the LMC

If we neglect scattering effects, the measured ultraviolet radiation is that part of the ultraviolet radiation emitted by the stellar population of the LMC that is not absorbed by interstellar dust. In the Galaxy infrared radiation is mainly caused by dust embedded in extended low density HII regions and by dust heated by the general interstellar radiation field (Mezger *et al.*, 1982; Cox *et al.*, 1986; Cox and Mezger, 1988). Hence the absorbed ultraviolet radiation is, together with absorbed visual radiation, directly related to the

**Figure 12.** Radiation fields in the Magellanic Clouds, expressed in terms of the average interstellar radiation field (after re-normalisation to  $T_d = 25$  K). Grey scales range from 0 – 10, contour levels are at 1, 3, 5, 7, 9, 15, 20. The resolution is  $8'$ .

Fig. 12.1. Radiation field density in the LMC.

Fig. 12.2. Radiation field density in the SMC.

infrared emission that IRAS measured. In general  $E(UV)_{abs} + E(UV)_{obs} = E(UV)_{emitted}$ . On large scales we may assume that dust densities are constant, and that the heating agents (OB stars) are distributed homogeneously. In that case, the absorbed fraction of the ultraviolet radiation field is derived from the observed infrared emission, and the remainder is observed directly. The amount of infrared emission in the Clouds is available from the foregoing. Also, ultraviolet data on the Clouds are available from spacecrafts and balloon platforms. Thus, we can in principle determine the total emitted ultraviolet radiation field strength in the Clouds. In Section 4.4 we discussed the radiation field of the absorbed ultraviolet component.

Vangioni-Flam *et al.* (1980) published integrated ultraviolet flux densities at 1690, 2200 and 3100 Å from low resolution  $1^\circ \times 3^\circ$  data previously published by Maucherat-Joubert *et al.* (1980). Studies of ultraviolet observations covering a large part of the LMC with spatial resolution of  $3' - 5'$  were made by Carruthers and Page (1977), Page and Carruthers (1981), with the Apollo 16 Far-ultraviolet camera/spectrograph on the moon (1050 – 1600 Å and 1200 – 1600 Å). A recently published study by Vuillemin (1988) shows a Skylab 2600 Å LMC map with a angular resolution of  $4' - 5'$ . These ultraviolet studies show us the concentrations of hot OB stars. Detailed ultraviolet data were obtained by Koornneef (1977) in the Greater 30 Doradus region with the Astronomical Netherlands Satellite ANS.

For a comparison of infrared with ultraviolet the observations of Vuillemin (1988) are very well suited; they cover only the SE-half of the LMC. In Fig. 13 we show an overlay of the infrared  $60\ \mu\text{m}$  intensity map and the line-of-sight dust temperatures, as grey scales, with the ultraviolet iso-contours of Vuillemin (1988). There is a global correspondence of the infrared and ultraviolet maps. The ultraviolet maps show the Greater 30 Doradus region and the LMC-Bar surrounded by some extended emission; N 11 and Constellation III are also strong UV emitters. Weak extended emission is visible on the published UV maps, but does not cover the extend of the infrared emission. On smaller scales there are differences, as might be expected from variations in dust density. Dust concentrations are expected to be associated with young star forming regions, which also represent concentrations of ultraviolet producing OB stars. The brightest UV point in the LMC is not the 30 Doradus HII region, but association 41 (Lucke and Hodge, 1970; in HII region N 119) in the LMC-Bar. In the infrared the 30 Doradus peak is much brighter than any other point in the LMC, 10 – 30 times brighter than N 119. Extinction measurements of Caplan and Deharveng (1983) show larger dust contents in the 30 Doradus region than in the area of N 119 in the Bar. This can explain the difference in relative observed ultraviolet radiation in these two regions.

The line-of-sight dust temperature map (Fig. 13.2) correlates better with the ultraviolet map than the infrared intensities (Fig. 13.1). Because the radiation field derived in Section 4.4 is directly related to dust temperatures, the relation between ultraviolet radiation and the radiation field needed to produce the infrared emission are also well correlated. The lowest UV-contour 0 (at  $1.52 \times 10^{-14}\ \text{erg cm}^{-2}\ \text{s}^{-1}\ \text{\AA}^{-1}$ ) of Vuillemin (1988) corresponds to a UV intensity of 0.040 MJy/sr and is enclosed by the dust temperature level of 31 K ( $\chi \approx 4$  in Section 4.4). The 3 times higher UV-contour labeled 2 entirely fits in temperatures above 34 K ( $\chi \approx 8$ ); the 5 times higher UV-contour labeled 4 above 36 K ( $\chi \approx 11$ ). Some ultraviolet emission peaks do not correlate at these

Figure 13. The relation between the LMC's infrared emission and line-of-sight dust temperature distribution as grey scales with  $8'$  resolution, and the ultraviolet iso-contours (Vuillemin, 1988). Lighter grey scales represent higher intensities or temperatures. The labels of the contours are explained in Vuillemin (1988).

Fig. 13.1.  $I_{60\mu m}$  and UV isocontours.

Fig. 13.2.  $T_d$  and UV isocontours.

**Figure 14.** The relation between the 8' infrared 60  $\mu$ m contour maps and the H $\alpha$  nebulosities (dark areas) obtained by Davies et al. (1976).

higher levels. Nine clear UV peaks fit well in the temperature maps, while on the other hand Lucke and Hodge association numbers 57, 61 (both in the Bar), 76, 63 (both in Constellation III) and 69 do not fit. From this comparison we conclude that there is good global correlation of infrared emission and especially dust temperature and its heating field with ultraviolet emission. OB stars are the most important heating agents.

We now look at the ultraviolet radiation field. We used the integrated 1690 Å data of Vangioni-Flam *et al.* (1980) and compared it to the Solar Neighbourhood (1 kpc<sup>2</sup>). We corrected the integrated Clouds' data for the sizes and obtained for the LMC a similar field as for the Solar Neighbourhood. For the SMC the average field is 3 times stronger. After UV extinction correction, Vangioni-Flam *et al.* (1980) derived intrinsic fields of 4 (LMC) resp. 5 (SMC) times stronger than the Solar Neighbourhood. From the emitted ultraviolet and infrared, we need intrinsic fields of 8 times (LMC) and 10 times (SMC) the Solar Neighbourhood field. These numbers are 2 times higher, and suggest that corrections based on  $A_\lambda = k_\lambda E_{B-V}$  underestimate the intrinsic ultraviolet emission. The uncertainties in the derivations of the intrinsic field are possibly of the same order.

### 5.2. Comparison of infrared radiation with H $\alpha$ emission

HII regions are formed around hot O- and B-type stars, and have much more intense radiation fields than the average interstellar medium. We therefore expect an indirect relation between H $\alpha$  emission and infrared emission. Integrated H $\alpha$  luminosities of the Clouds are given in Table 4. A detailed correlation of infrared sources with HII regions is given in Chapters II and III. We now compare the overall infrared maps with H $\alpha$  maps.

From H $\alpha$  plates presented by Davies *et al.* (1976) and Kennicutt and Hodge (1986) we see that there is less diffuse H $\alpha$  emission than infrared emission. In Fig. 14 we present overlay images of the H $\alpha$  nebulosities (Davies *et al.*, 1976) and the 60  $\mu$ m infrared radiation from the Clouds. We see that the infrared emission correlates very well qualitatively with the H $\alpha$  emission, especially at higher intensities. There is also a good correlation of the H $\alpha$  maps with the dust temperature map (compare Fig. 6 and Fig. 14).

The total infrared luminosity for Magellanic Clouds HII regions covers a wide range. The 30 Doradus peak is over 10 times more luminous than other, more representative regions. Although the presence of HII regions is indicated by strong infrared emission, the strength of the infrared emission is possibly not a good characterisation for HII regions.

### 5.3. Comparison of infrared with radio continuum radiation

Radio continuum radiation is produced by two mechanisms. The first one is thermal free-free emission and has a weak frequency dependence. It is associated with the young stellar population. The second mechanism is non-thermal radiation with a stronger frequency dependence and associated with the old stellar population (Sancisi and van der Kruit, 1981; Hummel, 1981) or with the young stellar population (Lequeux, 1971; Klein, 1982; Kennicutt, 1983). Galaxies show a combined spectrum of thermal radio continuum (relatively stronger in the HII regions) and non-thermal emission (relatively stronger in the extended disk). Several of these studies comment on a good large scale correlation between both thermal and non-thermal radio continuum emission.

In Fig. 15 we present overlays of the 60  $\mu$ m infrared contour maps with the 21-cm radio continuum grey scales maps of Haynes *et al.* (1986). In the radio continuum maps

**Figure 15.** The relation between the infrared  $60\ \mu\text{m}$  contour maps at  $15'$  and similar resolution radio continuum grey scales maps of Haynes *et al.* (1986). The higher radio intensities are lighter, via a saw-tooth.

Fig. 15.1. The LMC.

Fig. 15.2. The SMC.

some background sources are present. The SMC infrared maps show a similar size as the non-thermal 21-cm radio continuum disk. The infrared LMC emission area is somewhat smaller than the 21-cm 0.1 Jy/beam contour. On the IRAS Skyflux maps the 100  $\mu\text{m}$  emission covers the same area as the radio continuum in the North; but near the South end, Galactic infrared foreground filaments are projected on top of the LMC.

The IRAS infrared maps follow the radio continuum maps very well (see also Feitzinger *et al.*, 1988); qualitatively these two maps correlate better with each other than the infrared correlates with the  $\text{H}\alpha$  or ultraviolet data. The dust temperature also corresponds well with the radio continuum peaks. The influence of the lower sensitivity and the extinction on the ultraviolet and  $\text{H}\alpha$  data are the main reasons for the correlation differences with infrared emission compared to the radiocontinuum maps.

In the SMC there is a bright radio source in the Wing, just East of N 83 (number 21, at  $01^{\text{h}}09^{\text{m}}18^{\text{s}}$ ,  $-73^{\circ}30'00''$ ; in the list of Haynes *et al.*, 1986) which does not show up in the infrared. This may indicate that this radio source is a background galaxy.

## 6. Conclusions

We have presented low resolution ( $8'$ ) infrared maps of the Large and Small Magellanic Clouds (LMC and SMC) at 12, 25, 60 and 100  $\mu\text{m}$ . We have derived integrated infrared flux densities (Table 3). These integrated flux densities are sensitive to the background determination. Galaxies with similar infrared luminosities as the LMC are detectable up to distances of 27 Mpc; galaxies as the SMC up to about 8 Mpc.

The spectrum of the LMC is much like that of the SMC and of the irregular galaxy NGC 4449 (which is 4 times brighter); they represent warm dust spectra of 33 K. The nearby spiral galaxies M31 and M33 have cooler infrared spectra, and show higher mid-infrared (12 and 25  $\mu\text{m}$ ) excesses. The SMC shows a very small mid-infrared excess (15 %), while the LMC shows the same excess as NGC 4449 and M33, but a lower  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  ratio than M33. The infrared sizes are resp.  $6.6'$  and  $2.4'$ , which is a factor of two smaller than the cloud size for deep visual images. The infrared luminosities for the LMC are 12 times higher than for the SMC, representing a factor of 6 in 12 and 25  $\mu\text{m}$  surface brightness and 3 in 60 and 100  $\mu\text{m}$  surface brightness. The extrapolated total infrared luminosity of the LMC is  $9 \times 10^8 L_{\odot}$  and that of the SMC is  $8 \times 10^7 L_{\odot}$ . For the LMC 23 % of the stellar emission is re-emitted in the infrared, for the SMC this is 10 %. The luminosity-to-mass ratios are 1.3 and 0.12  $L_{\odot}/M_{\odot}$  for LMC and SMC, as compared to 1  $L_{\odot}/M_{\odot}$  for the Solar Neighbourhood.

The four infrared maps follow the optical emission of the Clouds; they are very similar. The 25  $\mu\text{m}$  band shows a much higher percentage of point source contribution to the total infrared flux density, than the other three bands, in effect reflecting the minimum at 25  $\mu\text{m}$  of the extended emission. The total flux density of unresolved sources in the LMC is 12 times higher than in the SMC, proportional to the ratio of the integrated flux densities. The Greater 30 Doradus region contains about 40 % of the total infrared emission of the LMC. The amount of low level extended emission in the SMC is relatively small. The line-of-sight dust temperature in the Clouds correlates well with the line-of-sight infrared intensities. Although the maps of  $T_d$  have steep gradients, there are in general three temperature regimes (HII-region warm-dust; diffuse cool-dust; intermediate). The

$T_{60-100\mu\text{m}}$  temperatures are 22 – 28 K for the diffuse component, 28 – 32 K for the intermediate and 32 – 45 K for the HII region component in both galaxies. The temperature derived from the ratio of 12 and 25  $\mu\text{m}$ ,  $T_{12-25\mu\text{m}}$ , is anti-correlated with infrared intensity and with  $T_{60-100\mu\text{m}}$ , while  $T_{25-60\mu\text{m}}$  correlates with  $T_{60-100\mu\text{m}}$  for hot areas (and anti-correlates with  $T_{12-25\mu\text{m}}$ ) and anti-correlates with  $T_{60-100\mu\text{m}}$  for cool areas (and correlates with  $T_{12-25\mu\text{m}}$ ).

The dust temperature decreases with increasing wavelength ( $\partial T/\partial \lambda < 0$ ). This shows that there is excess infrared emission at 12 and 25  $\mu\text{m}$  compared to the 'cool'-dust component responsible for the 60 and 100  $\mu\text{m}$  emission (see Chapter VI). We found infrared emission related to a number of H $\alpha$  supershells. The energy density of the interstellar radiation field in diffuse emission areas of the Clouds is about equal to the average Galactic interstellar radiation field (Mathis *et al.*, 1983). In the HII regions a difference is found of a factor of 10 – 20. From the infrared emission we derive 7 times stronger (absorbed) radiation fields in the Clouds than the local Galactic field, and about similar to the total Galactic field. Taking into account the emitted ultraviolet radiation, the total fields become 8 (LMC) and 10 (SMC) times stronger than the Solar Neighbourhood field.

The infrared radiation correlates well with other tracers of OB star distribution (ultraviolet radiation, H $\alpha$  nebulosities and radio continuum). The ultraviolet radiation strength is well correlated with dust temperatures. The H $\alpha$  and radio continuum distribution, both related to HII regions and a global component, have the same distribution over the face of each Cloud as the infrared intensity. The correlation between infrared and radio continuum is better than between any of the other data, largely reflecting sensitivity and extinction effects.

## Chapter VI

### PROPERTIES OF DUST IN THE MAGELLANIC CLOUDS

#### 1. Introduction and data presentation

Estimates of the amount of dust in the Magellanic Clouds have been based mainly on three methods, which are all subject to some controversy: reddening of individual Cloud stars (photometry and spectroscopy); surface extinction values (galaxy counts) and mapping of individual dust clouds by tracing their silhouette against the stellar background (for an overview see Israel, 1984). IRAS has now made it possible to observe thermal dust emission at mid- and far-infrared wavelengths; because this emission is optically thin all dust is observed.

We examine first the nature of the mid-infrared emission (*i.e.* 12 and 25  $\mu\text{m}$ ; Section 2). The nature of the 60 and 100  $\mu\text{m}$  emission of galaxies is relatively clear: dust heated by hot O- and B-type stars in extended low density HII regions or by the general interstellar radiation field (Mezger *et al.*, 1982; Cox *et al.*, 1986). However, extrapolation of the 100 and 60  $\mu\text{m}$  measurements towards shorter wavelengths does not explain the observed mid-infrared emission; this may indicate that a different population of dust particles produces the 12 and 25  $\mu\text{m}$  emission. In Section 3 we estimate the total mass of dust in the Clouds, together with the distribution of dust over the face of the Clouds. In Section 4 we investigate the relation of infrared emission and dust to atomic hydrogen.

The IRAS data contain information in four infrared wavelength bands at 12, 25, 60 and 100  $\mu\text{m}$ . The infrared maps used are the Additional Observation (AO) maps described in Section 2 of Chapter V. The mid-infrared distribution of Section 2 and the dust column density distribution of Section 3, have been estimated using the 8' resolution infrared maps (corresponding to a linear resolution of 135 pc at the distance of the Clouds). For HI, we used maps of Rohlfs *et al.* (1984) on the LMC and those of McGee and Newton (1981) on the SMC. These HI observations were obtained with the 64-m Parkes (CSIRO) radiotelescope, with a resolution of 15'. For the comparison we therefore convolved the infrared data to the HI resolution.

#### 2. Nature of dust emitting at mid-infrared wavelengths

Infrared emission at 12 and 25  $\mu\text{m}$  is remarkably strong. The mid-infrared emission of the Galaxy and its nature are discussed by Cox *et al.* (1986), revised by Cox and Mezger (1988). Similar strong mid-infrared intensities are seen in the nearest spiral galaxies M31 (Walterbos and Schwering, 1987) and M33 (Rice *et al.*, 1988a). The favoured explanation for the mid-infrared emission in these galaxies is the presence of very small grains (VSG; see Draine and Anderson, 1985) with radii  $a$  of  $0.4 \text{ nm} < a < 1.5 \text{ nm}$ ,  $\sim 100$  times smaller than "normal" large dust grains. The latter have sizes ranging from 5 nm to 1  $\mu\text{m}$ ; the size distribution depends on whether those grains have graphite or silicate cores — see

Appendix —;  $\langle a \rangle \approx 0.1 \mu\text{m}$ . The VSG are transiently heated by single (ultraviolet) photon absorption to high non-equilibrium temperatures of 300 – 1000 K (Sellgren, 1984; Puget *et al.*, 1985), and they emit infrared radiation while cooling down. A collection of VSG will thus have a distribution of temperatures with a small fraction of hot particles.

### 2.1. The Clouds' integrated mid-infrared excess emission

In Table 1 we summarize the infrared spectra of the Magellanic Clouds, and those of three colour temperatures  $T_c$  (which is defined as the temperature of the blackbody that fits two adjacent spectral bands). For reference we add the Clouds' stellar spectrum. A single temperature component cannot explain the full infrared spectrum from 12 to 100  $\mu\text{m}$ . The 60 – 100  $\mu\text{m}$  emission is dominated by cool dust with  $T_c \approx 44$  K. The colour temperature increases for the 25 – 60  $\mu\text{m}$  intensity ratios to 63 – 73 K, and is highest (230 – 250 K) for the 12 – 25  $\mu\text{m}$  ratio.

The 60 – 100  $\mu\text{m}$  emission of the Clouds can easily be explained by "normal" interstellar dust, even though it is warmer than dust in cool Galactic regions. The higher temperature is the consequence of on average stronger radiation fields than present in the Galaxy (for a quantitative analysis see Chapter V). The average 25 – 60  $\mu\text{m}$  colour temperature of 68 K is comparable to that of other galaxies. Extrapolation of the 100 and 60  $\mu\text{m}$  flux densities via a modified blackbody spectrum ( $\nu^{1.5} B_\nu(T_d)$ ) to 25  $\mu\text{m}$ , predicts 3 % of the observed 25  $\mu\text{m}$  emission. An extrapolation of the 60 and 25  $\mu\text{m}$  emission via a (modified) blackbody to 12  $\mu\text{m}$ , predicts much less than 1 % of the observed emission. The strength of the mid-infrared flux densities of the Clouds relative to the 60 and 100  $\mu\text{m}$  emission, shows that most of the 25  $\mu\text{m}$  emission and nearly all 12  $\mu\text{m}$  emission is unlikely to be produced by the "normal" grains that give rise to the cool dust emission. We call the mid-infrared emission that cannot be explained by the extrapolation of the cool dust emission, the *mid-infrared excess*.

Here we roughly estimate what fraction of 12 and 25  $\mu\text{m}$  emission could be due to integrated starlight. We extrapolate the integrated visual magnitudes of de Vaucouleurs (1960) at 4400 Å (B), 5500 Å (V) and 6250 Å using a 6700 K blackbody for both Clouds (corresponding to the spectrum of an F5 star, peaking at 7600 Å). As we neglect extinction effects the intrinsic average spectrum may be of somewhat earlier type. We predict only 77 Jy at 12  $\mu\text{m}$  in the LMC and 10 Jy in the SMC; *i.e.* 2 resp. 7 % of the observed  $f_{12\mu\text{m}}$ . The observed spectral shape of the mid-infrared emission excludes a large contribution of starlight at 25  $\mu\text{m}$ . Additional arguments follow from the distribution of the 12  $\mu\text{m}$  emission: the distribution of infrared emission does not follow the general stellar distribution (compare for instance the optical–stellar bar with the infrared–dust bar in the LMC; see Chapter V), but rather that of the younger population (embedded HII regions). Hence we conclude that direct starlight does not contribute significantly to the integrated mid-infrared flux density (see also Section 2.2).

We have compared the integrated infrared spectra of the Clouds to those of the galaxy M31 (Fig. 5 in Chapter V). The Clouds' spectra do not show a minimum at 25  $\mu\text{m}$ , as in the Galaxy (in high latitude dust clouds; see Boulanger *et al.*, 1985), M31 (Walterbos and Schwering, 1987) and M33 (Rice *et al.*, 1988a).

**Table 1.** Integrated flux densities of various temperature components compared to the Clouds, normalized to  $f_{60\mu\text{m}}$ .

$T_c$ (K)	Based on	$f_{12\mu\text{m}}$	$f_{25\mu\text{m}}$	$f_{60\mu\text{m}}$	$f_{100\mu\text{m}}$
SMC	IRAS Observations	0.02	0.06	1.0	2.0
LMC	IRAS Observations	0.05	0.11	1.0	2.2
240 K <sup>a)</sup>	12 – 25 $\mu\text{m}$	1.5	2.4	1.0	0.5
68 K	25 – 60 $\mu\text{m}$	$3 \times 10^{-4}$	0.1	1.0	1.0
44 K	60 – 100 $\mu\text{m}$	$4 \times 10^{-8}$	0.007	1.0	2.0
6700 K <sup>b)</sup>	0.44 – 0.625 $\mu\text{m}$	23.2	5.6	1.0	0.4

Notes to Table 1:

a) Colour temperatures based on adjacent bands.

b) The 6700 K component is based on the B, V and 6250 Å stellar data of de Vaucouleurs (1960; F5 spectrum).

**Table 2.** IRAS integrated infrared band ratios of some galaxies. <sup>a)</sup>

Object	$\frac{L_{\text{IR-tot}}}{L_{\odot}}$	$\frac{f_{12\mu\text{m}}}{f_{100\mu\text{m}}}$	$\frac{f_{12\mu\text{m}}}{f_{25\mu\text{m}}}$	$\frac{f_{25\mu\text{m}}}{f_{60\mu\text{m}}}$	$\frac{f_{60\mu\text{m}}}{f_{100\mu\text{m}}}$	Reference
LMC	$8.9 \times 10^8$	0.023	0.43	0.11	0.50	Chapter V.
SMC	$7.7 \times 10^7$	0.011	0.38	0.05	0.52	Chapter V.
MWG 1 <sup>b)</sup>	$1.5 \times 10^{10}$	0.027	0.96	0.07	0.43	Cox et al. (1986).
MWG 2	$8.6 \times 10^9$	0.034	0.51	0.28	0.24	Cox and Mezger (1988).
M31	$2.6 \times 10^9$	0.062	1.17	0.25	0.21	Walterbos and Schwing (1987).
M33	$1.1 \times 10^9$	0.034	1.02	0.10	0.34	Rice et al. (1988a).
NGC 4449	$5.8 \times 10^9$	0.029	0.45	0.13	0.49	Hunter et al. (1986).

Notes to Table 2:

a) The flux densities assume  $f_{\nu} \propto \nu^{-1}$ .b) For the Milky Way Galaxy, pre-IRAS MWG 1 data of Cox et al. (1986; Fig. 1 therein) and post-IRAS MWG 2 data of Cox and Mezger (1988; Fig. 2 therein) are given. Note the discrepancies between the pre- and post-IRAS ratios for the Galaxy. Both are obtained from data of the inner Galaxy ( $R < 8$  kpc). For MWG 2, the total infrared luminosity is obtained for  $\lambda > 25 \mu\text{m}$ .

Thus the Magellanic Clouds appear to show a mid-infrared excess which is, however, considerably smaller than that of the Local Group spiral galaxies and that of the Solar Neighbourhood. In Table 2 we give the total infrared luminosity and the IRAS flux density ratios for the Clouds, the Local Group spiral galaxies and the giant irregular galaxy NGC 4449. The ratios of the LMC are identical to those of NGC 4449. The SMC has the lowest  $f_{12\mu\text{m}}/f_{100\mu\text{m}}$ , and hence the smallest global mid-infrared excess. From the table we see that the ratio  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  is a stronger indicator for cirrus mid-infrared emission than the ratio  $f_{12\mu\text{m}}/f_{100\mu\text{m}}$  (used by *e.g.* Boulanger *et al.*, 1985). The irregular galaxies, the LMC, the SMC and NGC 4449 which have relatively high star formation rates per unit mass (see *e.g.* Lequeux, 1984), have a considerably lower  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  and higher  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$ . The least active galaxy of this sample, M31 (Walterbos and Schwing, 1987), has the highest  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  and lowest  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$ . Two sets of data are given for the Milky Way: pre-IRAS and post-IRAS data, which have remarkable differences (Table 2).

Figure 1. Colour-colour diagram of integrated galaxy data of Table 2. The plus sign represents the LMC, the SMC and NGC 4449. The large Local Group spiral galaxies (dots, open circles) are at the lower right. The dashed lines outline parts of the diagram occupied by galaxies (Helou, 1986). Note the two very different locations for the Milky Way, based on pre-IRAS (MWG 1) and post-IRAS (MWG 2) data.

Helou (1986) has showed that the ratio  $f_{12}/f_{25}$  is anti-correlated with the ratio  $f_{60}/f_{100}$  for integrated flux densities of galaxies. The six galaxies of Table 2 fit this picture; Fig. 1 presents these galaxies in Helou's colour-colour diagram. The three irregular galaxies occupy the same positions in the galaxy-area. The spiral galaxies are to the right of the diagram, indicating relatively cooler dust emission together with a high  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$ . Note the very different position of the Milky Way galaxy, after the post-IRAS revision. The average dust temperature in the Clouds is higher than in the Local Group spiral galaxies. A reduction in  $T_d$  for the Clouds would move them downward in the diagram, outside the galaxy-area. The positions of these galaxies in the diagram shows that it is difficult to reduce one of the two colours by a large factor while keeping the other constant.

## 2.2. The contribution of star-like objects to the mid-infrared excess emission

The nature of the mid-infrared (12 – 25  $\mu\text{m}$ ) excess emission is discussed in terms of the available IRAS spectral and spatial data on the Magellanic Clouds. We follow Cox *et al.* (1986) in discussing the options for the mid-infrared excess emission, and recall that the extrapolated mid-infrared luminosities of the Clouds are  $1.8 \times 10^8 L_\odot$  for the LMC and  $8.1 \times 10^6 L_\odot$  for the SMC (see Chapter V). We also note that the IRAS 12 and 25  $\mu\text{m}$  infrared maps resemble the 60 and 100  $\mu\text{m}$  maps. The latter certainly represent the distribution of warm and cool dust. We therefore expect the heating agents of the 12 and 25  $\mu\text{m}$  emission to be spatially related to the 60 and 100  $\mu\text{m}$  dust distribution.

### 2.2.1. Cool stellar photospheres; i.e. cool K- and M-giants (3000 – 4000 K)

First we estimate the percentage of the infrared emission that can be accounted for by cool giant stars. Dust grains are formed in the outer envelope of late type giants and are blown into the interstellar medium by stellar winds or supernova explosions. These stars, with temperatures of 3000 – 4000 K, have their maxima of the Planck curve  $B_\nu$  at 1.2 – 1.7  $\mu\text{m}$ .

We estimate the number of K- and M-type (super)giants by  $N_{K,M} = \Psi_{O,B} \tau_{K,M}/M_{O,B}$ ; here  $\Psi_{O,B}$  is the O- and B-type star formation rate,  $\tau_{K,M}$  is the lifetime of the K- and M-type stars and  $M_{O,B}$  the mass of O- and B- type stars. The star formation rate for stars with  $M > 10 M_\odot$ , is taken from Kennicutt and Hodge (1986); the values are 0.022 and 0.006  $M_\odot/\text{yr}$  for the LMC and SMC. The K- and M-type giant lifetime, of order  $3 \times 10^6$  yr, is estimated from Mihalas and Binney (1981) for stars with masses of 9 and 15  $M_\odot$ ; their total number then is  $5.5 \times 10^3$  for the LMC and  $1.5 \times 10^3$  for the SMC. As the luminosity of these stars is  $10^4 L_\odot$ , the total luminosity  $L_{\text{tot}}$ , integrated over all frequencies is  $5.5 \times 10^7$  and  $1.5 \times 10^7 L_\odot$ . In the infrared bands we estimate a luminosity from these stars of  $L_{\text{IRAS},\nu} = (\pi B_\nu(T) \Delta\nu_{\text{IRAS},\nu})/(\sigma T^4) L_{\text{tot}}$ . The highest fractions  $L_{\text{IRAS},\nu}/L_{\text{tot}}$  are found for the 3000 K stars: 0.43 % at 12  $\mu\text{m}$  and 0.042 % at 25  $\mu\text{m}$ . This implies monochromatic 12  $\mu\text{m}$  luminosities of  $2.4 \times 10^5 L_\odot$  for the LMC and  $6.5 \times 10^4 L_\odot$  for the SMC; respectively 0.4 and 3 % of the observed values. The contribution of stars in the 25  $\mu\text{m}$  band is 10 times less than that in the 12  $\mu\text{m}$  band. The image of the LMC-Bar in the mid-infrared (dust bar) is not identical to the optical (stellar) bar, in the SMC the stellar and dust bars coincide well. We conclude that photospheres of cool giant stars do not contribute significantly to the observed mid-infrared emission of the LMC and at best a little to that of the SMC.

### 2.2.2. Dust shells surrounding main sequence stars

Dust in shells surrounding main sequence stars can attain temperatures high enough to emit at mid-infrared wavelengths. The most luminous of these stars may, as a result of their higher ultraviolet and optical radiation, have a larger volume of hot dust around them. Although the number of early type hot stars is smaller than the number of late type cool stars, their contribution to mid-infrared emission is higher due to the larger luminosities. The contribution of dwarf stars is of no importance, even though there are many more of these stars. Typical peaks in  $f_\nu$  occur at wavelengths between 10 and 60  $\mu\text{m}$ ; the spectra of observed emission is indeed similar to that of such shells. In the Galaxy (Cox *et al.*, 1986) and M31 (Walterbos and Schwing, 1987), there are not enough of these embedded main sequence stars to be of importance. For the Galaxy, de Muizon and Rouan (1985) showed that their luminosity is roughly two orders of magnitude too low. We find that for the Magellanic Clouds the same applies.

In the LMC we have detected infrared — 12 and 25  $\mu\text{m}$  — emission from shells around Radcliffe LMC-stars R 66 and R 71; these stars are A- and B-type supergiants and they are among the brightest LMC-stars in the infrared, about 1 Jy at 12  $\mu\text{m}$ . They belong to the brightest visual stars (Feast *et al.*, 1960). The A-type supergiant star R 76 is an example of an LMC star with emission at 25 and 60  $\mu\text{m}$  from a dust shell. To estimate an upper limit for the total 12  $\mu\text{m}$  flux density of all Radcliffe-like stars, we sum the fluxes densities with positive detection quality (see Chapters II and III) and add detection limits for the rest of the stars. We find that only 30 Jy can be explained. Hence, we would need 160 of these Radcliffe samples to explain the LMC 12  $\mu\text{m}$  emission, too many to attribute to incompleteness of the bright star sample.

The Radcliffe sample of brightest SMC stars, contains 50 stars with infrared flux densities below the detection limit. Hence their (detection limit) sum is below 15 Jy; this is 10 % of the 12  $\mu\text{m}$  flux density but can be a large upper limit. Thus, we would need at least 10 times more of these stars; again this seems unlikely.

We conclude that there are not enough main sequence stars with dust shells in the Clouds to explain the mid-infrared excess emission. At best a small fraction of the mid-infrared excess might come from the brightest stars. The distribution of infrared emission supports this statement.

### 2.2.3. Late-type stars with thick dust shells (OH/IR stars and Miras)

The masses of late-type-stars with dust shells range from  $\sim 1 - 8 M_\odot$ . They are related to both young and evolved stellar populations (Habing, 1988). In the Galaxy, Cox *et al.* (1986) have estimated about half of the mid-infrared emission to come from these objects.

The first detection of an OH/IR star in the LMC is by Wood *et al.* (1986). Some objects in the source lists of Chapters II and III show weak infrared emission, with a spectrum typical of OH/IR stars. The brightest of these objects are distinguished relatively easily in the 25 – 60  $\mu\text{m}$  colour temperature maps as isolated peaks. Their 12 – 25  $\mu\text{m}$  ratio is low. At 60 and 100  $\mu\text{m}$  the OH/IR stars are too weak compared to the cool dust infrared emission to account for a large fraction (even if all 25  $\mu\text{m}$  emission comes from these objects only 10 % of the 60  $\mu\text{m}$  infrared emission can be accounted for).

We have estimated the number of OH/IR stars in the Clouds as follows. In the Milky Way Cox *et al.* (1986) have estimated this number to be  $6 \times 10^4$  with an average luminosity of  $2 \times 10^4 L_\odot$ . Recently Habing (1988) has estimated the average luminosity of these stars to be less: about  $4 \times 10^3 L_\odot$ . Using the Galactic stellar density  $N_{OH/IR}/N_{tot}$ , the number of OH/IR stars in the Clouds will be about 550 resp. 70. Using the density of Wolf-Rayet stars in the Solar Neighbourhood and the Clouds (Conti, 1987) and a density of 30 OH/IR stars  $\text{kpc}^{-3}$  (van der Veen, priv. comm.) in the Solar Neighbourhood we derive  $N_{OH/IR}/N_{WR} \approx 6.7$ . If we assume the same ratio to apply in the Clouds, we find similar numbers as above. We thus find total OH/IR star luminosities for the Clouds of  $2.2 \times 10^6$  and  $2.8 \times 10^5 L_\odot$ ; resp. 1 and 3 % of the mid-infrared emission; if we take a luminosity of  $2 \times 10^4 L_\odot$ , as Cox *et al.*, these percentages would be 5 times higher, but still inadequate.

Mira type variable stars can also contribute to mid-infrared emission. Their number is possibly 10 times larger than the number of OH/IR stars, but their luminosity is 3 times less at  $12 \mu\text{m}$  and 10 times less at  $25 \mu\text{m}$  (van der Veen, priv. comm.). Then their integrated luminosities would be 3 and 9 % for the LMC and SMC resp. at  $12 \mu\text{m}$  and 1 and 3 % at  $25 \mu\text{m}$ . The observed spectral shape of the Clouds is very different from that of Mira stars; therefore to explain the mid-infrared emission by Mira stars would lead to problems for the  $25 \mu\text{m}$  flux density. We conclude that neither OH/IR stars, nor Mira type stars are responsible for the bulk of the mid-infrared excess emission.

#### 2.2.4. Proto stellar objects or young stars still embedded in dust

We have attempted to quantify the contribution from these objects, by calculating the expected infrared luminosity for an Initial Mass Function  $\phi(m)$  (IMF; Miller and Scalo, 1978) at the present Star Formation Rate  $\Psi(t)$  (SFR). The emitted infrared luminosity is given by

$$L_{IR} = \frac{\int_{m_{low}}^{m_{up}} dm \phi(m) \int_{t_0}^{t_f} dt \Psi(t) f_{IR/*}(m, t) L_*(m, t)}{\int_{m_{low}}^{m_{up}} dm m \phi(m)} \approx \frac{\sum_m (\phi(m) L_*(m, t) t_*)}{\sum_m m \phi(m)} \Psi(t_0) f_{IR/*}(m, t). \quad (1)$$

We have used the power-law approximation of the Miller–Scalo IMF (Mezger, 1985) with  $m_{low} = 0.1 M_\odot$  and  $m_{up} = 60 M_\odot$ . The IMF in the Galaxy is similar to the IMF in the LMC (Scalo, 1987); we assume the same for the SMC IMF. The evolutionary pre-main sequence tracks in the Hertzsprung–Russel diagram, luminosities  $L_*(m, t)$  and time scales  $t_*$ , were taken from Mihalas and Binney (1981), for stars from  $0.5$  to  $50 M_\odot$ . The major contribution to the infrared luminosity comes from stars with  $M \approx 10 M_\odot$  (for a  $10 M_\odot$  star  $L_*(m) = 2 \times 10^3 L_\odot$ ,  $t_* = 3.8 \times 10^5 \text{ yr}$ ). The luminosity has been weighed towards the main-sequence at the end of the tracks as the life-time is larger. The total star formation rates have been taken from Kennicutt and Hodge (1986) and are  $0.14$  and  $0.038 M_\odot/\text{yr}$  for the LMC and SMC resp. For the fraction of the emission of these objects in the infrared, we used  $f_{IR/*}(m, t) = 0.5$ : early in their evolution the shell is optically thick at  $12 \mu\text{m}$

and most emission will be emitted at longer infrared wavelengths; while close to the main sequence, the shell breaks up and visible light can travel through.

For proto stellar objects or young stars embedded in dust, the adopted numerical values result in luminosities of  $8 \times 10^6$  and  $2 \times 10^6 L_{\odot}$  which are 4 and 25 % of the measured total mid-infrared luminosities. For the LMC only a small fraction of the mid-infrared emission can be explained in this way. For the SMC on the other hand, these objects can produce a reasonably large fraction of the mid-infrared emission.

A few proto stellar objects have been found in the LMC (K2 and P2 in N 159; Gatley *et al.*, 1981; Jones *et al.*, 1986) and SMC (K2 in N 76B; Gatley *et al.*, 1982). The protostars in N 159 have an infrared luminosity of  $\sim 2 \times 10^4 L_{\odot}$ ; this is only 4 % of the infrared luminosity of the nebula N 159 in which they are embedded ( $10^6 L_{\odot}$ ; see Werner *et al.*, 1978). The protostar in N 76B in the SMC has a luminosity of  $\sim 4 \times 10^3 L_{\odot}$ . From the infrared maps we find an infrared luminosity for the nebula N 76B of about  $4 \times 10^5 L_{\odot}$ . Hence, only 1 % of the emission of the nebula is produced by the protostar. These objects were found in an active HII regions where we expect most protostars to occur. Although possibly some protostars were not detected in the regions, the total number of these objects remains small, and hence their luminosity at most only a few percent of the total observed mid-infrared luminosity. The fact that the relative  $12 \mu\text{m}$  excess anti-correlates with the HII regions (Section 2.3.2) indicates that young stars are not the main cause of the excess emission. The number of observed proto stars in the SMC shows that the calculated contribution of 25 % is probably an overestimate.

**Table 3.** Maximum stellar contribution to mid-infrared emission from the Clouds. <sup>a)</sup>

Nature	L M C (%)		S M C (%)	
	$L_{12\mu\text{m}}$	$L_{25\mu\text{m}}$	$L_{12\mu\text{m}}$	$L_{25\mu\text{m}}$
Clouds' luminosity ( $10^6 L_{\odot}$ )	57	51	2.5	2.5
Late type giants: K-, M-stars	0.4	0.05	3	0.3
Main sequence stars with dust shells	0.6	0.6	10	10
OH/IR stars	1	1	3	3
Mira stars	3	1	9	3
Proto stars	4	4	25	25
Total stellar contribution (upper limit)	9	7	50	41

Note to Table 3:

- a) The spectrum of the dust shells around main sequence stars and of the protostars has been assumed to be similar to that of the Clouds.

### 2.3. The nature of the mid-infrared excess emission

#### 2.3.1. Very small grains mixed with large grains in infrared cirrus

The possible contributions to the mid-infrared emission of all components described above are summarized in Table 3. Together they can account for at most about 10 % (LMC) and 50 % (SMC) of the emission. For the SMC this number is much higher than for the LMC, because we assume Galactic properties in our estimations while the mid-infrared excess of the SMC is rather small, even compared to the LMC. We now consider the hypothesis that, at least, the remaining 90 and 50 % of the mid-infrared emission is caused by non-equilibrium emission of very small grains. Although alternatives for very small grains are not excluded, we will from now on adopt the hypothesis of Puget *et al.* (1985).

These grains can then be understood as being large (50 atom) molecules: Polycyclic Aromatic Hydrocarbons (PAHs). Their heat content  $C_V(T)$  is small due to their small size; hence absorption of single ultraviolet photons  $h\nu$  increase their initial temperature  $T_i$  to  $T_f$ , by a large amount ( $h\nu = \int_{T_i}^{T_f} C_V(T) dT$ ). Such grains, especially the smallest, can be destroyed easily by single ultraviolet photons if  $T_f > T_{subl}$  (with  $T_{subl}$  the sublimation temperature of  $\gtrsim 1000$  K). The cooling process of the excited grain happens fast compared to the time-scale for new photon encounters; they are not in equilibrium. The observed infrared radiation is the temperature-weighted emission of the ensemble of these small grains.

Small grains can be produced in different ways: photoelectric disruption of large grains may occur in strong radiation fields, and shocks in the interstellar medium modify the grain size distribution. Strong radiation fields influence the minimum grain radius  $a$  by sublimation of the smallest grains. This radius is not very sensitive to radiation fields of stars later than type A, or the general interstellar radiation field ( $a_{min} = 0.4 - 0.5$  nm; Puget *et al.*, 1985). For earlier type stars there is a large increase in  $a_{min}$  to about 1.0 nm in the radiation field of an O5-star at a distance of 1 pc.

In our Galaxy these very small grains (PAHs) are supposedly well mixed with the larger grains on 100 pc scales (Cox *et al.*, 1986); it explains the observed similarity between 12 and 25  $\mu\text{m}$  emission with 60 and 100  $\mu\text{m}$  emission. In various Galactic cirrus areas their presence has been suggested. De Vries (1986) and Boulanger *et al.* (1985) have studied high latitude dust clouds; the strength of their mid-infrared emission is most easily explained by the PAHs. A new study by Boulanger *et al.* (1988) also shows strong evidence for these grains. Beichmann *et al.* (1988) found a correlation between 100  $\mu\text{m}$  intensity and  $^{13}\text{CO}$  in the dark cloud Barnard 5, but an anti-correlation between 12  $\mu\text{m}$  and CO line emission. This is interpreted as due to the presence of a thin shell of PAHs.

From pre-IRAS observations of the Milky Way galaxy, Cox *et al.* (1986) calculated that the mid-infrared emission is produced equally by the OH/IR stars and small grains. In other nearby galaxies (M31; Walterbos and Schwering (1987), M33; Rice *et al.* (1988a)) only these grains are necessary to explain the mid-infrared emission.

The integrated mid-infrared excess emission of the Clouds is less than that in the nearby spiral galaxies ( $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  in Table 2). If very small grains are responsible for the excess in the Local Group spiral galaxies, this excess is comparatively small in the Clouds and small grains should easily be capable of producing the observed excess. Also,

the flux density ratios of the Clouds obey the  $f_{12\mu\text{m}}/f_{25\mu\text{m}} - f_{60\mu\text{m}}/f_{100\mu\text{m}}$  relation in the diagram of Helou (1986); see Fig. 1: the mid-infrared excess is indeed what we expect for galaxies with the observed  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$ .

From Draine and Anderson (1985), we derive the relative spectrum of very small grains (with radii  $0.3 \text{ nm} < a < 3.0 \text{ nm}$ ) to be 1, 3, 4.5 and 0 in the 12, 25, 60 and 100  $\mu\text{m}$  bands (see Appendix). The integrated Clouds flux densities are taken from Chapter V. We have fitted the 12 and 25  $\mu\text{m}$  integrated emission from the Clouds, neglecting other possible contributors, with the small grain spectrum. The fit is very accurate at 25  $\mu\text{m}$  and within 10 – 20 % of the observed flux density at 12  $\mu\text{m}$ . Small grains contribute 17 % of the 60  $\mu\text{m}$  flux density in the LMC and 8 % in the SMC. Comparing the result on M31 (Walterbos and Schwering, 1987), very small grains in the Clouds do not give a large contribution to the 60  $\mu\text{m}$  flux densities. The main reason for this is the higher Clouds' average  $T_d$  of the "normal" grains. We conclude that the mid-infrared emission of the Clouds can be well explained by very small grains.

### 2.3.2. The distribution of the mid-infrared excess emission

After global estimates for the very small grain contribution to the mid-infrared emission, we now look at the distribution and positional differences in the mid-infrared excess of the Clouds. Table 6 of Chapter V already shows that the area South of the 30 Doradus region, with on average  $f_{12\mu\text{m}}/f_{25\mu\text{m}} = 0.96$  and  $f_{60\mu\text{m}}/f_{100\mu\text{m}} = 0.3$ , closely resembles typical Galactic cirrus areas. On the other hand, the 30 Doradus region shows infrared flux density ratios similar to that of Galactic HII regions.

Indications of spatial variations of the mid-infrared excess over the face of the Clouds come from the IRAS maps at 12 and 25  $\mu\text{m}$  (Chapter V; Fig. 2 and 3). At no position in these maps a single temperature component, based on the 60 and 100  $\mu\text{m}$  data, can explain the observed 12 or 25  $\mu\text{m}$  emission. A region of special interest is the area South of the nebula N 159 (Henize, 1956) in the LMC; its 12 – 25  $\mu\text{m}$  colour temperature ( $f_{12\mu\text{m}}/f_{25\mu\text{m}}$ ) is higher compared to any other area and the 12  $\mu\text{m}$  intensity from this region is relatively high. (Chapter V; Table 6). We find a typical Galactic cirrus infrared spectrum in this region with  $T_{12-25} = 335 \text{ K}$ ; HII region complexes have typically  $T_{12-25} = 160 \text{ K}$ .

To quantify the mid-infrared excess emission we modelled pixel-by-pixel the expected 12 and 25  $\mu\text{m}$  maps by extrapolating the longer wavelength data (taking  $\epsilon_\nu \propto \nu^n$ ,  $n = 1.5$ ). For the 12  $\mu\text{m}$  model we used the 60 – 100  $\mu\text{m}$  maps (with  $n = 1.5$ ) and also the 25 – 60  $\mu\text{m}$  maps (with  $n = 0$ ); for the 25  $\mu\text{m}$  model we have only the 60 and 100  $\mu\text{m}$  data. The model is defined by

$$I_\nu^{\text{mod}} \equiv I_{\nu_1} \frac{B_\nu(T_{\nu_1-\nu_2})}{B_{\nu_1}(T_{\nu_1-\nu_2})} \left(\frac{\nu}{\nu_1}\right)^n. \quad (2)$$

As explained in the previous section, only small fractions of the mid-infrared emission can be accounted for by extrapolated far-infrared emission, and  $(I_\nu - I_\nu^{\text{mod}})$  maps are very similar to infrared maps in Chapter V. For this reason we show in Fig. 2 and 3 the *relative excess emission maps* at 12 and 25  $\mu\text{m}$ , defined by

$$R_\nu \equiv \frac{I_\nu - I_\nu^{\text{mod}}}{I_\nu^{\text{mod}}}. \quad (3)$$

This (relative) excess emission shows an anti-correlation with the infrared brightness distribution at all wavelengths. It also anti-correlates with  $T_d$  (from 60 and 100  $\mu\text{m}$ ), but it correlates with the 12 – 25  $\mu\text{m}$  colour temperature. Very systematically, HII regions show the lowest excess emission, both in the 12 and 25  $\mu\text{m}$  extrapolation.

This is a very important result. In HII regions, dust particles are on average much closer to the heating stars than in the main body of the Clouds. One would thus expect HII regions to have a more significant hot component, and thus a larger mid-infrared excess than other parts of the Clouds, contrary to what is observed !

The fact that the mid-infrared excess is associated with the diffuse medium rather than the HII regions is a powerful indicator that (a) the mid-infrared excess is caused by VSGs in the diffuse medium and (b) that these VSGs are largely absent in or near HII regions. The depletion of VSG emission in HII regions is even stronger than suggested by Fig. 2 and 3, because as noted above, in HII regions there will also be a mid-infrared excess contribution by normal dust heated to higher temperatures which is absent or weak outside HII regions. With respect to this, note that in the 1' KAO beam 30 Doradus (Werner *et al.*, 1978) shows indeed enhanced emission at 30  $\mu\text{m}$  correlated with 50 – 100  $\mu\text{m}$  temperatures.

In the extrapolations, we have assumed that the dust emissivity in HII regions is constant with wavelength, and that a single temperature applies. More realistically, the emissivity may change with wavelength and instead of a single temperature throughout, temperature gradients apply.

**Figure 2.** LMC mid-infrared excess emission (8' resolution). In all maps, of  $8^\circ \times 8^\circ$  size, darker grey scales indicate higher map values. The relative infrared excess emission at frequency  $\nu$  is defined as  $R_\nu \equiv (I_\nu - I_\nu^{\text{mod}})/I_\nu^{\text{mod}}$ . See also pages 206 – 207.

Fig. 2.3. LMC  $R_{25\mu\text{m}}$  map, with model 60 – 100  $\mu\text{m}$  emission.  
 Grey scale range: 30 – 400.

Fig. 2.4. LMC 12  $\mu\text{m}$  cirrus intensity map.

Grey scales: 0 – 9.6 MJy/sr; contours are at 0.15, 0.37, 0.74, 1.9, 3.7, 5.6, 7.4 MJy/sr.

Fig. 2.5. LMC 25  $\mu\text{m}$  cirrus intensity map.

Grey scales: 0 – 7.8 MJy/sr; contours are at 0.39, 0.97, 1.9, 4.8 MJy/sr.

We have attempted to empirically compensate for these effects in the following manner. We determine the mean infrared spectrum of the brightest HII regions in both LMC and SMC. We assume that cirrus emission is negligible in these lines-of-sight. We then determine, from  $\nu^{1.5} B_\nu(T_d)$ , the average dust temperature  $T_d$  (HII), and then reduce the effect of (both) emissivity law changes and temperature gradients to an apparent change in emissivity by fitting the observed 12 and 25  $\mu\text{m}$  points to  $\nu^n B_\nu(T_d(\text{HII}))$ . Thus, for 60  $\mu\text{m}$   $< \lambda < 100 \mu\text{m}$ ,  $n \equiv 1.5$ , while for 12 and 25  $\mu\text{m}$  higher values for  $n$  are found. These values obviously have no direct physical meaning; they merely serve as convenient parameters to describe the observed HII region infrared spectrum. Numerical values are given in Tables 4 and 5. We now assume these values for  $n$  to hold for *all* normal grains in the Clouds, and use it to extrapolate the "normal grain emission" maps at 60  $\mu\text{m}$  and 100  $\mu\text{m}$  to 12  $\mu\text{m}$  and 25  $\mu\text{m}$ . The difference between the observed maps and these extrapolated maps are the maps of the VSG (cirrus) emission at 12  $\mu\text{m}$  and 25  $\mu\text{m}$  (Fig. 2.4, 2.5, 3.4 and 3.5). Strictly speaking, these maps are lower limits to the cirrus emission outside the HII regions since large grain temperature gradients are probably less important in the diffuse medium than in HII region environments. As the extrapolation to 25  $\mu\text{m}$  is over a smaller wavelength range than the 12  $\mu\text{m}$ , the 25  $\mu\text{m}$  cirrus maps are more reliable than the 12  $\mu\text{m}$  maps. At 25  $\mu\text{m}$ , about 25 % of the Clouds integrated emission appears due to cirrus, at 12  $\mu\text{m}$  about 90 % (Tables 4 and 5).

**Figure 3.** SMC mid-infrared excess emission (8' resolution). In all maps, of 4'8 x 4'8 size, darker grey scales indicate higher map values. Note the spatial scale difference between the LMC maps and the SMC maps in this chapter. The relative infrared excess emission at frequency  $\nu$  is defined as  $R_\nu \equiv (I_\nu - I_\nu^{\text{mod}})/I_\nu^{\text{mod}}$ . See also pages 209 – 210.

$f_{\text{HII}}/f_{\text{tot}}$	0.05	0.72	—	—

Notes to Tables 4 and 5:

- a) The HII region infrared spectrum  $f_{\nu, \text{HII}}$  has been determined by adding fluxes at positions with  $I_{100\mu\text{m}} > 40 \text{ MJy/sr}$ . It and the Planck blackbody function  $B_{\nu}(T_d)$  are given relative to the 100  $\mu\text{m}$  values.
- b)  $T_d$  has been derived assuming  $f_{\nu} \propto \nu^{1.5} B_{\nu}(T_d)$  at 60 and 100  $\mu\text{m}$ .
- c)  $n_i$  is the average emissivity exponent between bands  $i$  and  $j$ , and is derived from  $f_i/f_j = (\nu_i/\nu_j)^n (B_i(T_d)/B_j(T_d))$ , with  $i$  and  $j$  adjacent bands.
- d)  $\langle n \rangle$  gives the average value of  $n$  for  $j \equiv 100 \mu\text{m}$ ; hence the average emissivity exponent between band  $i$  and the 100  $\mu\text{m}$  band.
- e) The integrated flux densities are taken from Chapter V. The mid-infrared cirrus and HII contributions are normalized to the integrated fluxes.

### 2.3.3. Conclusion: mid-infrared emission in the Magellanic Clouds

The anti-correlation of the relative 12  $\mu\text{m}$  excess with the dust temperature, as shown in Fig. 2 and 3, is possibly caused by the destructive nature of the strong radiation field near hot stars, on these small grains (see Section 2.3.1). Close to HII regions PAHs are hit by photons with energies higher than the sublimation energy of the grains, resulting in a destruction of the smallest grains. Recently Boulanger *et al.* (1988) found that in the California Nebula, the 12  $\mu\text{m}$  intensity profile peaks farther away from the star  $\xi$  Per than the 100  $\mu\text{m}$  intensity profile. This difference is interpreted as a result of the destruction of PAHs close to the star. For a radiation field 50 times stronger than the Solar Neighbourhood field they calculated that 80 % of the PAHs are destroyed. Thus we expect the mid-infrared excess to be smallest where the ultraviolet radiation field is strongest in the Clouds. In Chapter V we showed that the radiation fields in Magellanic Cloud HII regions are possibly even stronger than 50 times the Solar Neighbourhood field; in Fig.

4.1 we show the relation between ultraviolet emission (Vuillemin, 1988) and the 25  $\mu\text{m}$  cirrus map. Note the generally strong anti-correlation. Fig. 4.2 shows the relation of the ultraviolet emission to  $T_{12-25\mu\text{m}}$ ; again an anti-correlation is seen. Hence, our conclusion that Cloud HII regions are largely, if not entirely void of these PAHs is clearly supported: the derived distribution of cirrus emission is what is to be expected from PAHs.

We conclude that the most probable nature of the mid-infrared excess emission in the Magellanic Clouds are the very small grains (PAHs). We also find that these VSGs are present in significant quantities mainly in the diffuse interstellar medium. More specifically, HII regions and their immediate environments appear to be largely free of VSGs which is probably due to radiative destruction of these small particles. The best estimates for the distribution of VSGs is shown in Fig. 2.5 (LMC) and 3.5 (SMC).

### 3. Amount of emitting dust in the Magellanic Clouds

Dust grains absorb starlight, thereby heating up and emitting in the infrared. Thus, infrared radiation is re-emitted starlight. For this mechanism, theoretical in-band fluxes have been calculated for a range of dust temperatures and are presented in the Appendix. It is assumed that only one type of dust radiates at 60 and 100  $\mu\text{m}$ , that it is located at a fixed distance  $D$  from us (53 kpc for the LMC and 63 kpc for the SMC; Humphreys, 1984) and that it is optically thin at these wavelengths. The equations used to obtain dust masses  $M$  and dust (mass) column densities  $M_d$  are

$$M = \frac{f_\nu D^2}{\kappa_\nu B_\nu(T_d)} \quad (4)$$

and

$$M_d = \frac{I_\nu D^2 \Delta\Omega}{\kappa_\nu B_\nu(T_d)}, \quad (5)$$

where  $\Delta\Omega$  is the solid angle of the area corresponding to 1  $\text{cm}^2$  at the distance  $D$ . The equation to calculate the dust mass is essentially the one given by Hildebrand (1983), although we use a somewhat different dust emissivity (see the Appendix for a discussion). This assumed absorptivity,  $\kappa_\nu (\text{cm}^2/\text{gram}) = 40 (\lambda/100 \mu\text{m})^{-1.5}$ , results in somewhat lower ( $\sim 0.9$ ) temperatures and dust masses.

#### 3.1. Dust mass estimated from global emission

Straightforward use of the integrated 60 and 100  $\mu\text{m}$  infrared flux densities yields a total dust mass of  $1.4 \times 10^5 M_\odot$  for the LMC and  $1.2 \times 10^4 M_\odot$  for the SMC, at an average (60 – 100  $\mu\text{m}$ )  $T_d$  of 33 K (see Chapter V). These values are lower limits as they do not take into account actual spatial variations in temperature (in the line-of-sight or in the sky plane). Because of the strong dependence of thermal dust emission on temperature ( $I_\nu \propto M_d \kappa_\nu B_\nu(T_d) \propto M_d T_d^{4+n}$ ), mass estimates of dust with a range of temperatures are biased towards the hottest dust in the beam. For this reason, the assumption of a

**Figure 4.** Overlays showing the relation between mid-infrared excess emission (grey scales) and ultraviolet radiation (contours) in the LMC. Darker grey scales represent more intense excess emission. The contours are taken from Viullemin (1988; added labels are described in that paper). Note the different orientation of these maps with respect to the other maps in this chapter.

Fig. 4.1. LMC 25  $\mu\text{m}$  cirrus intensity map (grey scales as in Fig. 2.5) and ultraviolet emission (contours).

Fig. 4.2. LMC  $T_{12-25\mu\text{m}}$  map (V.7.1, grey scales as in Fig. V.7.1) and ultraviolet emission (contours).

single temperature derived from emission ratios tends to underestimate the cool and total amounts of dust mass present.

In Section 2.3.1 we calculated that 17 % of the 60  $\mu\text{m}$  flux densities of the LMC and 8 % of that of the SMC are produced by very small grains. Correcting the 60  $\mu\text{m}$  intensities for small grains contributions,  $T_d$  drops to 31 and 32 K respectively, resulting in an increase in dust mass of about 34 and 15 % respectively.

The mass of the hot dust component (with  $T_d \gtrsim 200$  K) is calculated from the integrated 12 and 25  $\mu\text{m}$  flux densities using Equation 4. We derived masses of  $2 M_\odot$  for the LMC and  $0.1 M_\odot$  for the SMC, negligible compared to the mass of the cool and warm dust component.

### 3.2. Dust mass estimated from line-of-sight temperature distribution

The above estimate, derived from global properties can be improved by taking into account the structure of the Clouds as revealed by the IRAS maps. First, we consider the effect of varying temperature across the Clouds, *i.e.* the temperature distribution over the sky plane. We still assume that in each line-of-sight dust is adequately represented by the single line-of-sight temperature derived from the 60 to 100  $\mu\text{m}$  emission ratio. Maps of the line-of-sight temperature can then be combined with *e.g.* 100  $\mu\text{m}$  (or 60  $\mu\text{m}$ ) intensity maps to yield dust column density maps. Integration of these column density maps over the face of the Clouds then yields the total dust mass. The mass so derived will be higher than the mass derived from the global emission because dust at temperatures lower than the emissivity-weighted global mean is now more adequately represented: dust with lower  $T_d$  has a much smaller emissivity; therefore, its column density and mass has to be higher to produce the same intensity as hotter dust. Spatial resolution is also a factor of importance. With finite sensitivity, convolution to lower resolution increases the detectability of low-surface brightness regions. If, as is the case at the edges of the LMC, such regions also have relatively low dust temperatures, they may contribute significantly to the local mass without being an important contributor to the total infrared intensity. It turns out that this effect is not very important for the SMC. Obviously, further degradation of the spatial resolution leads to diminishing returns as relatively cool regions become progressively more blended with hotter regions. The limit, of course, is the reduction of the object to a point source, where we have reduced the observations to the case discussed in Section 3.1.

Use of the line-of-sight temperature distribution in the Clouds raises the lower limit to the dust mass of the LMC to  $2.0 \times 10^5 M_\odot$  (increase of 45 %) and  $1.2 \times 10^4 M_\odot$  for the SMC (no increase). If the contribution of PAHs to the 60  $\mu\text{m}$  emission is taken into account the masses are resp. 24 and 15 % higher. They are still lower limits, because we have still ignored possible variations in dust temperature in the line-of-sight.

If the clouds are relatively flat and seen face-on, line-of-sight depths are small. If these depths are of order 150 pc or less, we expect only small temperature gradients in the line-of-sight, and the estimate would be essentially correct. If line-of-sight depths are much larger than this, cool dust may be present in significant amounts, and we would have underestimated the total mass possibly by a large factor. To estimate the potential range of dust masses, we assume (unrealistically) that all observed infrared emission originates in the coolest dust component. In this way, we can derive an upper limit to the total amount of dust as a function of the assumed cold dust temperature. The results of this

calculation are given in Table 6. Since the Magellanic Clouds are characterized by stronger radiation fields than the Solar Neighbourhood (Chapter V) and by lower dust abundances (Koornneef, 1984), we do not expect dust in the Clouds to be colder than dust in the Solar Neighbourhood. If most of the dust were at 15 K, the upper limit to the mass is two orders of magnitude higher than the lower limit we have just derived. More realistically, for 20 K, the range between lower and upper mass limits is only an order of magnitude. Thus, our first attempts yield a mass estimate that — barring systematic errors in the Chicago assumptions (Hildebrand, 1983) — is correct to within an order of magnitude.

**Table 6.** *Integrated dust mass from 100  $\mu$ m flux densities assuming fixed and variable dust temperatures.*

Line-of-sight $T_d$	$2.0 \times 10^5$	$1.2 \times 10^4$
Decomposition of $T_d$	$6.2 \times 10^5$	$1.6 \times 10^4$

### 3.3. Dust mass estimated from decomposition of line-of-sight temperatures

In order to further improve our mass estimate, we have decomposed the emission from each line-of-sight into emission from dust at different temperatures. The procedure is as follows. We start with the lowest observed line-of-sight temperature  $T_0$  (at the Cloud edges) covering at least a few per cent of the total Cloud surface area. The surface brightness corresponding to this temperature is then extrapolated over the full face of the Clouds, and subtracted from the observed maps. With a suitable temperature step  $\Delta T$ , this procedure is then repeated on the remaining map, but now extrapolating over the surface area with line-of-sight temperatures larger than  $T_1$ ; yielding a map of dust emitting at temperature  $T_1 = T_0 + \Delta T$ , and a new set of intensity maps now only containing dust at temperatures  $T > T_1$ . The procedure is then repeated until the highest observed temperature is reached, so that we have decomposed the observed maps into a set of intensity maps at different, but constant temperatures. The sum of the intensity maps reproduces the observed total intensity maps, and the constant temperature maps can be

converted into column density maps. Summing these constant temperature column density maps yields the total column density map, and summing that map yields the total mass.

In effect, the method redistributes observed infrared intensities to temperatures lower than the line-of-sight temperature while keeping the total intensity constant and equal to the observed intensity. This procedure then yields a "best" estimate for the total mass, because it neither assumes that all dust radiates at the line-of-sight temperature (*i.e.* close to the maximum temperature in that line-of-sight), nor that all dust radiates at the lowest temperature seen anywhere in the Clouds. The results are listed in Table 7, as a function of temperature step  $\Delta T$  used in the decomposition. Obviously, the result becomes more accurate with smaller steps. For the LMC, the mass derived in this way converges at  $6.2 \times 10^5 M_\odot$ , and for the SMC at  $1.6 \times 10^4 M_\odot$ .

Table 7. Total dust masses for line-of-sight temperature decomposition.

$\Delta T$ (K)	$M_{LMC}/M_\odot$	$M_{SMC}/M_\odot$	$M_{MWS}/M_{I_{0.8}}^a$
<i>T-range</i>	22 - 43	27 - 43	23 - 29
30 <sup>b)</sup>	$2.0 \times 10^5$	$1.2 \times 10^4$	1.00
15	$2.0 \times 10^5$	$1.3 \times 10^4$	1.00
10	$2.4 \times 10^5$	$1.5 \times 10^4$	1.00
5	$4.2 \times 10^5$	$1.5 \times 10^4$	1.00
2.5	$5.6 \times 10^5$	$1.5 \times 10^4$	1.07
1	$5.7 \times 10^5$	$1.6 \times 10^4$	1.24
0.5	$6.2 \times 10^5$	$1.6 \times 10^4$	1.27

Notes to Table 7:

- a) The Galactic foreground data of Chapter IV has been used to give the relative increase in the integrated dust mass. The foreground column density is normalized to  $1386 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ . The foreground data has been convolved to  $35^\circ$  resolution, the same linear resolution as the infrared data on the LMC.
- b) The value for  $\Delta T = 30$  K corresponds to the mass calculation from the line-of-sight temperatures.

There are two basic assumptions underlying this estimate. The first is that in each line-of-sight, dust is present at all temperatures between the lowest temperature seen in the Clouds and the emissivity-weighted line-of-sight temperature. As mentioned before, this is probably not true if the Clouds have only small line-of-sight depths. In that case, the above values are overestimates. The second assumption is that the lowest observed temperature in the Clouds is indeed the lowest dust temperature present. Although we have confidence in this assumption, we must point out that colder dust could be present, in which case the above values are underestimates (see Section 3.4). From this, and the preceding section, we conclude that realistic estimates for the mass of cool ( $T_d \approx 25$  K)

dust present in the Magellanic Clouds are between  $2$  and  $6 \times 10^5 M_\odot$  for the LMC and between  $1.2$  and  $1.6 \times 10^4 M_\odot$  for the SMC. A possible contribution by cold (15 K) dust is discussed in Section 3.4.

In the LMC, about 50 % of the total surface area emits at line-of-sight temperatures  $< 30$  K. Our decomposition leads to the situation that in fact 90 % of all LMC dust emits at  $T_d < 30$  K, contributing 60 % of the observed  $100 \mu\text{m}$  intensity. Average temperatures as opposed to emissivity-weighted temperatures are 26 K for the LMC and 31 K for the SMC. The small mass range for the SMC reflects the fact that it contains only a small area with line-of-sight temperatures  $< 30$  K. Extrapolation of the LMC decomposition on SMC dust shows that dust with temperatures between 22 and 27 K has a mass of  $(0 - 2) \times 10^4 M_\odot$ . For comparison purposes a similar decomposition has been applied on the Galactic foreground of Chapter IV. The foreground maps were first convolved to a resolution of  $35''$  (i.e. identical linear resolution as on the LMC). The temperatures then range from 23 to 29 K, showing a similar lowest dust temperature as in the LMC. We find an increase in dust column densities for the foreground emission of 27 %.

### 3.4. The cold dust mass

The mass of cold ( $T_d < 20$  K) dust is a potential problem. Because  $I_\nu \propto M_d \kappa_\nu T_d^{4+n}$ , large masses of cold dust will not contribute commensurably to intensity and hence, will go unnoticed with the presence of a reasonable amount of cool ( $\sim 25$  K) or warm ( $\sim 50$  K) dust (cf. Table 6). In the preceding sections we have assumed that cold dust is present in insignificant amounts. In this section we will take a closer look at this assumption.

Chini *et al.* (1984) observed continuum emission from several spiral galaxies at 1-mm. We have combined their data with integrated IRAS flux densities (Rice *et al.*, 1988b). From the 60 and  $100 \mu\text{m}$  IRAS data we calculated dust temperatures  $T_d$  and masses  $M_{T_d}$ , and predicted 1-mm flux densities. Comparison of predicted with observed flux densities then gives the ratio  $M_{15K}/M_{T_d}$ . For the six spiral galaxies we find  $M_{15K} \approx M_{T_d}$  (with the exception of the peculiar galaxy NGC 4736). Due to the Clouds lower metallicities (Dufour, 1984) and higher star formation activity (Lequeux, 1984), we expect more cold dust in these large spiral galaxies than in the Magellanic Clouds. This comparison therefore sets the upper limit of cold dust in the Magellanic Clouds equal to the dust mass based on integrated flux densities (Section 3.1):  $1.4 \times 10^5 M_\odot$  for the LMC and  $1.2 \times 10^4 M_\odot$  for the SMC.

According to Cox *et al.* (1986) dust associated with quiescent molecular clouds in our Galaxy has a temperature of about 15 K, so that  $B_\nu$  peaks at infrared wavelengths of  $340 \mu\text{m}$ . The total molecular gas content of the Galaxy equals the atomic gas content. The total molecular hydrogen content of the Clouds is estimated by Cohen *et al.* (1988) and Rubio *et al.* (1988) to be about 1/3 of the atomic hydrogen content, i.e.  $1.8 \times 10^8 M_\odot$  for the LMC and  $1.6 \times 10^8 M_\odot$  for the SMC. According to Cox *et al.* (1986), in the Galaxy both HI and H<sub>2</sub> clouds have the same gas-to-dust ratio. If we adopt the same for the Clouds, we find from the global estimates of cool dust that  $M_c = 5 \times 10^4 M_\odot$  for the LMC and  $5 \times 10^3 M_\odot$  for the SMC. Thus, realistic estimates for a cold (15 K) dust component are  $(1.0 \pm 0.5) \times 10^5 M_\odot$  for the LMC, and  $(0.8 \pm 0.4) \times 10^4 M_\odot$  for the SMC.

### 3.5. The total dust mass of the Magellanic Clouds

In Table 8 we summarize the dust masses of the Clouds for the different temperature components (also gas masses and the total dynamic mass are given). For the LMC we derive a total dust mass of  $M_{LMC} = (5.5 \pm 2) \times 10^5 M_{\odot}$  and for the SMC we find  $M_{SMC} = (2.4^{+2.2}_{-0.2}) \times 10^4 M_{\odot}$ . The correction for a contribution of PAHs at  $60 \mu\text{m}$  has been applied. The large relative error in the SMC value results from the unknown dust component with temperatures between 23 and 27 K.

Table 8. Masses in the Magellanic Clouds (in  $M_{\odot}$ ).

Property		LMC	SMC	Reference
<i>Dust masses:</i>				
Warm + cool	$M_{w+c}$	$4.1 \times 10^5$	$1.4 \times 10^4$	Section 3.3.
Correction for PAHs		$0.4 \times 10^5$	$0.2 \times 10^4$	Section 3.1.
Cold	$M_c$	$1.0 \times 10^5$	$0.8 \times 10^4$	Section 3.4.
Total	$M_d$	$5.5 \times 10^5$	$2.4 \times 10^4$	Section 3.5.
<i>Gas masses:</i>				
HI	$M_{HI}$	$5.4 \times 10^8$	$4.8 \times 10^8$	McGee and Milton (1966), Hindman (1967).
H <sub>2</sub>	$M_{H_2}$	$1.8 \times 10^8$	$1.6 \times 10^8$	Cohen et al. (1988), Rubio et al. (1988).
He	$M_{He}$	$1.6 \times 10^7$	$1.4 \times 10^7$	Lequeux (1984).
Total	$M_{gas}$	$8.8 \times 10^8$	$7.8 \times 10^8$	
<i>Dynamic mass:</i>				
Total	$M_{dyn}$	$6.0 \times 10^9$	$1.5 \times 10^9$	McGee and Milton (1966), Hindman (1967).

### 3.6. The distribution of the warm and cool dust

The dust column density maps of the Magellanic Clouds are shown in Fig. 5. As mentioned in Section 3.1, derived line-of-sight temperatures may overestimate the average line-of-sight temperature and dust column densities may therefore be underestimated. This effect may be progressively more important in the higher temperature regions (*e.g.* the Greater 30 Doradus Region).

In general there is good agreement between the infrared maps (see Chapter V; Fig. 1 and 2) and the dust column density maps. High dust column densities appear on peaks in the dust temperature maps (Fig. 5 in Chapter V). This suggests that overcorrection

**Figure 5.** Dust column density maps ( $M_d$ ) of the Magellanic Clouds, based on line-of-sight infrared data, at a resolution of  $8'$ .

**Fig. 5.1.** The LMC. Grey scales range from  $1 - 300 \times 10^6 M_\odot/\text{sr}$ . Darker grey scales correspond to higher dust column densities. Contours are at  $10, 20, 40, 60, 100, 200, 275 \times 10^6 M_\odot/\text{sr}$ . At the distance of the LMC ( $53 \text{ kpc}$ ) a column density of  $10^6 M_\odot/\text{sr}$  corresponds to a mass of  $3.17 \times 10^{16} \text{ H-atoms cm}^{-2}$ .

**Fig. 5.2.** The SMC. Grey scales range from  $1.4 - 54 \times 10^6 M_\odot/\text{sr}$ . Darker grey scales correspond to higher dust column densities. Contours are at  $10, 20, 30, 40, 50 \times 10^6 M_\odot/\text{sr}$ . At the distance of the SMC ( $63 \text{ kpc}$ ) a column density of  $10^6 M_\odot/\text{sr}$  corresponds to a mass of  $4.48 \times 10^{16} \text{ H-atoms cm}^{-2}$ .

Figure 6. LMC 6' pixel-to-pixel scatter diagrams of the dust column density  $M_d$  ( $10^6 M_\odot/\text{sr}$ ), dust temperature  $T_d$  (K) and 100  $\mu\text{m}$  intensity  $I_{100\mu\text{m}}$  (MJy/sr).

Figure 7. SMC 3' pixel-to-pixel scatter diagrams of the dust column density  $M_d$  ( $10^6 M_\odot/\text{sr}$ ), dust temperature  $T_d$  (K) and 100  $\mu\text{m}$  intensity  $I_{100\mu\text{m}}$  (MJy/sr).

for temperature is relatively small in regions with high dust temperature. The relation between  $M_d$  and  $I_{100\mu m}$ , between  $M_d$  and  $T_d$  and between  $I_{100\mu m}$  and  $T_d$  are given in pixel-to-pixel scatter diagrams in Fig. 6 and 7 for both Clouds. The dust column densities are uncorrelated with temperature. The continuously changing slope in Fig. 6.2 and 7.2 shows the temperature effect in the intensity maps.

In the LMC, derived dust column densities peak in the 30 Doradus region at  $250 \times 10^6 M_\odot/\text{sr}$ . This area looks point-like on the map, indicating a relatively compact dust concentration. The diffuse LMC dust component varies between  $(3 - 8) \times 10^6$ , while about half the face of the LMC reaches above  $10 \times 10^6 M_\odot/\text{sr}$ . The Bar has an enhanced column density  $(20 - 70) \times 10^6$  while some HII regions have even higher densities of dust (N 11, N 140, N 210:  $(20 - 90) \times 10^6 M_\odot/\text{sr}$ ). In the LMC, a large dust mass concentration is located in the Greater Doradus Region. This area is about  $1.5 \times 1$  kpc in size and it coincides with the well known star formation region, containing the HII regions 30 Doradus, N 160, N 158 and N 159. In a large area of this complex densities are above  $20 \times 10^6 M_\odot/\text{sr}$ . Due to the higher temperature of the dust grains, dust column densities could be underestimated somewhat more in the Greater 30 Doradus Region than in other regions, increasing the contrast. In Table 9 we give integrated line-of-sight dust masses for the LMC areas defined in Chapter V; atomic hydrogen and cirrus contents are also given, as well as local gas-to-dust ratios (based on line-of-sight data). Note the large amount of dust and gas in the Greater Doradus Region. The relative mid-infrared excess emission is much less in the Greater Doradus Region than in the other regions (see Section 2.3.2).

Table 9. Dust and gas in some selected areas in the LMC <sup>a)</sup>.

Property (Unit)	Bar	Shapley Const. III	Doradus Region Greater	LMC South	LMC Rest
Equivalent area $\Omega$ ( $10^{-3}$ sr / %)	1.22 7	2.11 12	1.78 10	0.85 5	11.5 66
$M_d$ ( $10^4 M_\odot$ )	2.8	2.4	5.5	1.9	7.1
$T_d$ (K)	33	32	36	27	31
$f_{12\mu m, \text{cirrus}} / f_{12\mu m, \text{area}}$ (%)	100	97	53	97	81
$f_{12\mu m, \text{cirrus}} / f_{12\mu m, \text{tot}}$ (%)	16	11	17	5	29
$f_{25\mu m, \text{cirrus}} / f_{25\mu m, \text{area}}$ (%)	26	31	6	43	40
$f_{25\mu m, \text{cirrus}} / f_{25\mu m, \text{tot}}$ (%)	3	3	3	1	10
$\sigma_d$ ( $10^7 M_\odot/\text{sr}$ )	2.3	1.1	3.1	2.2	0.6
$M_{HI}$ ( $10^7 M_\odot$ )	3.5	4.0	7.5	3.9	14.0
$M_{HI}/M_d$ (—)	1250	1670	1360	2050	1970

In contrast to the LMC, there is no large dust concentration visible in the column density map of the SMC. There are 5 clear peaks in the SMC dust distribution: two in the SW-Bar, a main one at  $\sim 55 \times 10^6 M_\odot/\text{sr}$  and one just East of it at  $\sim 25 \times 10^6 M_\odot/\text{sr}$ ; in the NE-Bar N 76 shows a peak ( $\sim 33 \times 10^6 M_\odot/\text{sr}$ ), while the complex N 83/84 dominates the dust content of the Wing ( $\sim 32 \times 10^6 M_\odot/\text{sr}$ ). Although high in infrared intensity, N 66 in the NE-Bar is not a strong peak in the dust column density map ( $\sim 25 \times 10^6 M_\odot/\text{sr}$ ). The increased infrared in this region is therefore mainly a temperature effect. The entire SMC-Bar shows densities of  $(12 - 18) \times 10^6 M_\odot/\text{sr}$  while the extended component is  $(2 - 10) \times 10^6 M_\odot/\text{sr}$  surrounding the Bar and connecting it to the SMC-Wing. In Table 10 we give integrated dust masses for the same areas as defined in Chapter V. We see that the NE-Bar and SW-Bar have identical dust properties, but that the dust and cirrus properties in the Shapley Wing are different; the Wing shows a much higher gas-to-dust ratio (based on line-of-sight data) than the Bar region and the cirrus emission at  $12 \mu\text{m}$  is much smaller.

Table 10. Dust and gas in some selected areas in the SMC <sup>a)</sup>.

Property (Unit)	NE-Bar	SW-Bar	Shapley Wing
Equivalent Area $\Omega$ ( $10^{-3} \text{ sr} / \%$ )	3.06 39	2.96 38	1.75 23
$M_d$ ( $10^3 M_\odot$ )	4.8	6.4	1.0
$T_d$ (K)	34	34	33
$f_{12\mu\text{m},\text{cirrus}}/f_{12\mu\text{m},\text{area}}$ (%)	100	99	37
$f_{12\mu\text{m},\text{cirrus}}/f_{12\mu\text{m},\text{tot}}$ (%)	34	55	6
$f_{25\mu\text{m},\text{cirrus}}/f_{25\mu\text{m},\text{area}}$ (%)	31	27	23
$f_{25\mu\text{m},\text{cirrus}}/f_{25\mu\text{m},\text{tot}}$ (%)	11	13	4
$\sigma_d$ ( $10^6 M_\odot/\text{sr}$ )	1.6	2.2	0.6
$M_{\text{HI}}$ ( $10^7 M_\odot$ )	13.7	17.5	8.8
$M_{\text{HI}}/M_d$ (-)	28500	27300	91700

Note to Tables 9 and 10:

- a) The total flux density in each area related to cirrus at 12 and  $25 \mu\text{m}$  has been calculated relative to the total Clouds' flux densities and relative to the flux densities in the specific areas.

Dust masses are calculated from line-of-sight data.

#### 4. Comparison of infrared radiation and dust with atomic hydrogen

##### 4.1. Infrared and atomic hydrogen emission

We compared the infrared maps with HI observations of Rohlfs *et al.* (1984) on the LMC and of McGee and Newton (1981) on the SMC. HI column densities are higher in the SMC than in the LMC. Integration of the HI data shows that the SMC map contains 90 % and, due to the limited field size, the LMC map only 60 % of the integrated HI mass of Hindman (1967) and McGee and Milton (1966); this does not influence our discussion. Large scale HI maps of Mathewson and Ford (1984), have a highest contour enclosing both Clouds at  $3 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ . The HI column density, corresponding to the infrared sizes of Chapter V are about  $25 \times 10^{20}$  for the SMC and  $10 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$  for the LMC, well above the map noise level. Fig. 8.1 and 8.3 give overlays of the infrared 100  $\mu\text{m}$  intensity of the Clouds with HI column densities. Note the good qualitative correlation between the infrared and the HI emission on these large (15') scales.

The LMC HI and infrared emission peak in the 30 Doradus region, but the HI peak is much more extended. The LMC-Bar is not as pronounced in HI as it is at 100  $\mu\text{m}$ ; in the infrared maps it is seen mainly due to the emission from individual HII regions. SMC areas with weak extended HI emission are not prominent at 100  $\mu\text{m}$ . Note some remarkable differences between 100  $\mu\text{m}$  emission and HI data. In the SMC the HII region N 66 is a bright peak at 100  $\mu\text{m}$  but it does not show up in the HI map, as in fact it did not in the dust column density map either. In the LMC, HII region N 55 has a similar high infrared-to-HI ratio, but here there is a clear dust column density peak. Possibly, gas is completely blown away, or most of the gas is in molecular form. New ESO-SEST CO observations show the presence of a compact CO cloud in this region (Israel, priv. comm.).

**Figure 8.** Relation between infrared maps and HI maps (at 15' resolution). See pages 224 - 225.

Fig. 8.1 overlays LMC  $I_{100\mu\text{m}}$  with  $N_{\text{HI}}$ .  $N_{\text{HI}}$  grey scales range from  $(0 - 45) \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ ; darker grey scales indicate higher HI column densities. LMC  $I_{100\mu\text{m}}$  contours are at 5, 10, 20, 40, 60, 100, 200, 400, 600 MJy/sr.

Fig. 8.2 shows the LMC ratio  $I_{100\mu\text{m}}/N_{\text{HI}}$ . Grey scales range from  $(0.1 - 5) \times 10^{-14}$ ; darker grey scales indicate higher ratios. Contours are at 0.5, 0.75, 1.0, 1.5, 2.0, 10.0 ( $\text{MJy sr}^{-1})/(10^{20}$  H-atoms  $\text{cm}^{-2}$ ).

Fig. 8.3 overlays SMC  $I_{100\mu\text{m}}$  with  $N_{\text{HI}}$ .  $N_{\text{HI}}$  grey scales range from  $(0 - 110) \times 10^{20}$  H-atoms  $\text{cm}^{-2}$ ; darker grey scales indicate higher HI column densities. SMC  $I_{100\mu\text{m}}$  contours are at 2, 5, 10, 20, 30, 40, 50 MJy/sr.

Fig. 8.4 shows the SMC ratio  $I_{100\mu\text{m}}/N_{\text{HI}}$ . Grey scales range from  $(0.1 - 0.7) \times 10^{-14}$ ; darker grey scales indicate higher ratios. Contours are at 0.05, 0.075, 0.1, 0.2, 0.3, 0.4, 0.5 ( $\text{MJy sr}^{-1})/(10^{20}$  H-atoms  $\text{cm}^{-2}$ ).

**Figure 10.** SMC 3' pixel-to-pixel scatter diagrams for  $^{10}\log I_{\nu, \text{IR}} - ^{10}\log N_{\text{HI}}$  (with  $I_{\nu, \text{IR}}$  in MJy/sr and  $N_{\text{HI}}$  in  $10^{20}$  H-atoms  $\text{cm}^{-2}$ ). The fitted lines, which show the relation between the infrared and HI emission are discussed in the text. The large scatter at 12 and 25  $\mu\text{m}$  at low infrared intensities are due to noise effects and are not considered in the fit.

The integrated Clouds' 100  $\mu\text{m}$  flux densities and HI masses result in ratios  $I_{100\mu\text{m}}/N_{\text{HI}} \approx 0.9 \text{ MJy sr}^{-1}/10^{20} \text{ H-atoms cm}^{-2}$  for the LMC and 0.06 for the SMC. To compare the IRAS 100  $\mu\text{m}$  AO maps with the HI maps, we obtained ratio maps  $I_{100\mu\text{m}}/N_{\text{HI}}$  (Fig. 8.2 and 8.4). A comparison of the low-level diffuse infrared and HI emission ( $N_{\text{HI}} < 10^{21} \text{ H-atoms cm}^{-2}$ ) gives ratios of  $0.9 \pm 0.5$  in the LMC and  $0.08 \pm 0.05 \text{ MJy sr}^{-1}/10^{20} \text{ H-atoms cm}^{-2}$  in the SMC. For the LMC-Bar we find ratios of 2 – 4 and for 30 Doradus  $I_{100\mu\text{m}}/N_{\text{HI}} > 15$ , the maximum in the LMC. The SMC-Bar has ratios of 0.15 – 0.30, peaking just above 0.7 in the HII region N 66. The peak in the SW-Bar has  $I_{100\mu\text{m}}/N_{\text{HI}} \approx 0.5$ . We see that the infrared-to-HI ratio varies even at low infrared and HI intensity levels. The average ratio is 6 – 20 times higher in the LMC than in the SMC; this ratio difference increases with infrared intensity. It is a result of the SMC's relatively weak infrared emission, together with the high HI content. At low levels the LMC ratio is about 1.5 times higher than the Galactic ratio derived in Chapter IV. A difference of 10 % in  $T_d$  can account for this factor.

In Fig. 9 (LMC) and Fig. 10 (SMC) we show pixel-to-pixel scatter diagrams of the four IRAS infrared bands with the HI column densities. A summary of the fitted power-law relations,  $I_\nu = \alpha_\nu \text{ HI}^{\beta_\nu}$ , is given in Table 11. The fits are also shown in the figures; they are not very accurate due to the large scatter for individual pixels, especially at low intensity levels. But they show that infrared emission increases much faster than the HI column densities ( $2 < \beta_\nu < 3$ ). The SMC exponents  $\beta_\nu$  are 0.5 lower than the LMC exponents in all four bands. For the SMC  $\alpha_\nu$  is 10 times lower at 60 and 100  $\mu\text{m}$ . The variations in absolute values  $\alpha_\nu$  for the different bands is real, but the reality of the differences in  $\beta_\nu$  cannot be validated due to the large scatter in the diagrams, and it probably reflects the fitting uncertainties. Similar results were found for the 60 and 100  $\mu\text{m}$  bands for the Galactic foreground towards the Clouds (Chapter IV).

Explanations for ratio variations in the Galactic foreground are discussed in Chapter IV. Several causes can be: variations in dust temperature, possible optical depth effect in the HI or variations in the dust-to-gas ratio. We refer to Chapter IV for a more detailed discussion. In the Clouds we have a larger temperature range than in the Galactic foreground, allowing for larger infrared intensity variations. This discussion again shows that  $I_{100\mu\text{m}}/N_{\text{HI}}$  should *not* be used as a global characteristic of galaxies. Variations of this ratio for different areas in galaxies could give rise to large errors.

**Figure 11.** Relation between dust and HI column densities (at 15' resolution). See pages 229 – 230.

Fig. 11.1 shows the LMC dust mass density overlayed on the HI column density map. Dust mass contours are at 5, 10, 20, 40, 70, 100, 130, 160, 190  $\times 10^6 M_\odot/\text{sr}$ .  $N_{\text{HI}}$  grey scales range from 0 – 45  $\times 10^{20} \text{ H-atoms cm}^{-2}$ ; darker grey scales indicate higher HI column densities.

Fig. 11.2 shows the LMC dust-to-atomic gas mass ratio. Grey scales range from 0 – 2  $\times 10^{-3}$ ; darker grey scales indicate higher ratios; the top grey scales are in 30 Doradus and N55. Contours are at 2, 4, 6, 8, 10, 15  $\times 10^{-4}$ .

Fig. 11.3 shows the SMC dust mass density overlayed on the HI column density. Dust mass contours are at 2, 5, 10, 15, 20, 25, 30, 40  $\times 10^6 M_\odot/\text{sr}$ .  $N_{\text{HI}}$  grey scales range from 0 – 110  $\times 10^{20} \text{ H-atoms cm}^{-2}$ ; darker grey scales indicate higher HI column densities.

Fig. 11.4 shows the SMC dust-to-atomic gas mass ratio. Grey scales range from 0 – 1.2  $\times 10^{-4}$ ; darker grey scales indicate higher ratios; the top grey scales are in N 76 and SW-Bar. Contour values are at 2, 4, 6, 8, 10  $\times 10^{-5}$ .

#### 4.2. Dust and atomic hydrogen column densities

The infrared optical depths, calculated as  $\tau_\nu = I_\nu/B_\nu(T_{60-100\mu\text{m}})$  are small and peak at  $0.3 \times 10^{-3}$  in the LMC (30 Doradus region) and at  $0.4 \times 10^{-4}$  in the SMC (SW-Bar). Hydrogen column densities might be underestimated if the optical depth for HI is not small; this may affect the peaks of the  $N_{\text{HI}}$  distribution (*e.g.* the Greater 30 Doradus Region). Generally, we will assume optically thin HI emission from the Clouds.

A comparison of HI column densities with line-of-sight dust column densities is shown in Fig. 11; overlays of HI and dust are given together with the dimensionless  $M_d/M_{\text{HI}}$  mass ratio maps. Locally there are variations in the derived dust-to-gas ratio (Fig. 11.2 and 11.4).  $M_d/M_{\text{HI}}$  is higher in HII regions (infrared emission peaks), while the diffuse infrared emission has a low ratio. In the figures the dust-to-gas ratio correlates with line-of-sight temperatures and infrared emission, but less than  $I_{100\mu\text{m}}/N_{\text{HI}}$ . In the LMC, peaks in the dust-to-gas ratio occur at 30 Doradus of  $2.1 \times 10^{-3}$ , and in N 55 of  $2.5 \times 10^{-3}$ . In the SMC peaks occur at N 76 ( $1.5 \times 10^{-4}$ ), the SW-Bar ( $1.5 \times 10^{-4}$ ) and N 83/84 ( $0.8 \times 10^{-4}$ ). Rather than a different gas-to-dust ratio, this result may indicate the presence of significant amounts of molecular gas in these locations. Fig. 12 shows the relation between  $T_d$  and  $M_d$  with  $N_{\text{HI}}$  in pixel-to-pixel scatter diagrams. The temperatures are rather uncorrelated with  $N_{\text{HI}}$ ; on average there is a small increase in  $T_d$  with  $N_{\text{HI}}$ .  $M_d$  is better correlated with  $N_{\text{HI}}$ , however clear diversions from the straight line occur, especially at high HI column densities. From these diagrams we derive values for  $M_d/M_{\text{HI}}$  of 1/1800 (LMC) and 1/23000 (SMC), with a 40 % spread; Fig. 12 also shows these derived linear relations with their error bars. Correcting for the line-of-sight decomposition in temperature and the contribution by cold dust will give ratios 2 – 3 times higher. A complete discussion about the gas-to-dust ratio, related to other observations, will be given in the next chapter. Here we only note that in particular the increase of  $M_d/M_{\text{HI}}$  with increasing  $N_{\text{HI}}$  at  $N_{\text{HI}} > 4 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$  may indicate the presence of (unseen) molecular gas.

**Table 11.** Relations of infrared and dust with HI.<sup>a)</sup>

Data	$\alpha_\nu$	LMC		$\alpha_\nu$	SMC	
		$\beta_\nu$	Fig.		$\beta_\nu$	Fig.
$I_{12\mu\text{m}}$	0.00025	2.8	9.1	0.000039	2.3	10.1
$I_{25\mu\text{m}}$	0.00017	3.1	9.2	0.0000060	2.8	10.2
$I_{60\mu\text{m}}$	0.0036	2.9	9.3	0.00033	2.5	10.3
$I_{100\mu\text{m}}$	0.017	2.7	9.4	0.0017	2.2	10.4
$I_{60\mu\text{m}}/I_{100\mu\text{m}}$	0.2 – 1.0	—	—	0.3 – 1.0	—	—
$T_d$ (K)	23 – 43	—	12.1	28 – 43	—	12.3
$M_{\text{HI}}/M_d$	1800	—	12.2	23000	—	12.4

Note to Table 11:

a) The specific intensities  $I_\nu$  are in MJy/sr and the HI column densities are in  $10^{20}$  H-atoms  $\text{cm}^{-2}$ .

**Figure 12.** Pixel-to-pixel scatter diagrams for both Clouds, showing the relation of  $T_d$  (K) and  $M_d$  ( $10^6 M_\odot/\text{sr}$ ) with  $N_{\text{HI}}$  ( $10^{20} \text{ H-atoms cm}^{-2}$ ). LMC pixels are  $6'$ , SMC pixels  $3'$  in size. In the dust-to-gas mass relation diagrams, the solid straight lines are fitted average dust-to-gas ratios, while the dashed ones are derived by using the global properties.

## 5. Conclusions

As the Local Group spiral galaxies, the Magellanic Clouds contain 12 and  $25 \mu\text{m}$  excess emission relative to the extrapolated cool dust emission. This excess is weak compared to that in the spiral galaxies, and the SMC excess is only half that of the LMC excess, which is similar to the excess emission in the giant irregular galaxy NGC 4449. The Clouds show low integrated  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  ratios. The ratios  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  and  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  place the Clouds in the middle of the galaxy area in Helou's (1986) colour-colour diagram.

The nature of the mid-infrared emission in the Clouds is discussed. For both Clouds, very small grains (PAHs) heated to high non-equilibrium temperatures by single photon hits are the most likely explanation for the mid-infrared excess. In the SMC 25 % of the SMC mid-infrared emission might be caused by (proto) stellar objects. We created maps of the relative mid-infrared excess; these maps anti-correlate with infrared emission. We have derived 12 and 25  $\mu\text{m}$  cirrus maps, by removing the large grain population, which show an anti-correlation with the ultraviolet radiation field. Detailed studies show that the excess and cirrus emission is less in HII regions. In the SMC, the Shapley Wing likewise shows little excess emission.

We have presented dust column density maps for the Magellanic Clouds. In the LMC the main complex of dust is the Greater 30 Doradus region. In the SMC no large dust mass concentration is present, and the bright HII region N 66 shows up only marginally; here high infrared intensities are caused by high dust temperatures. Mostly the effects of high dust content and high temperature combine to produce observed infrared radiation.

From the dust column density maps we have derived total dust masses for the cool (25 K) and warm ( $> 30$  K) dust components in the Magellanic Clouds. We have estimated the amount of unobserved cold ( $< 20$  K) dust in the Clouds using 1-mm observations of other galaxies and CO observations of the Clouds. The amount of hot dust, emitting at 12 and 25  $\mu\text{m}$  is negligible compared to the mass of cool dust. We obtain dust masses of  $M_{LMC} = (5.5 \pm 2) \times 10^5 M_{\odot}$  and  $M_{SMC} = (2.4^{+2.2}_{-0.2}) \times 10^4 M_{\odot}$ .

We discuss the relation between infrared 100  $\mu\text{m}$  intensity and the neutral hydrogen column density for the Clouds. The ratio  $I_{100\mu\text{m}}/N_{HI}$  varies strongly over the face of the Clouds. Scatter diagrams show that  $I_{\nu} \propto N_{HI}^{2.5}$ . Therefore  $I_{100\mu\text{m}}/N_{HI}$  should not be used as a global characteristic of galaxies, nor should it be extrapolated over areas in a single galaxies. The dust column density map correlates well with the HI map. The dust-to-gas ratio varies over the face of the Clouds, but less strong as  $I_{100\mu\text{m}}/N_{HI}$ ; its use is more justified.

## Chapter VII

### DUST IN THE MAGELLANIC CLOUDS

#### 1. Introduction

The Magellanic Clouds are the closest neighbour galaxies of the Milky Way. Their distances of 53 kpc (LMC) and 63 kpc (SMC) (Humphreys, 1984) imply for any (diffraction limited) instrument linear resolutions roughly ten times better than on the closest spiral galaxies M31 (690 kpc) and M33 (720 kpc), and 250 times better than on similar (dwarf) irregular galaxies in the Virgo cluster (15 Mpc). Detection limits for point sources are more than 100 times better than for all other galaxies. This makes the Clouds ideal objects to study their structure in detail and compare them with detailed studies in our Galaxy, and also to compare integrated properties with those of other galaxies.

In this chapter we discuss in Section 2 the infrared characteristics of the Magellanic Clouds, as derived in this thesis. This contains a summary of the foreground extinction, the Clouds' global infrared properties, a discussion of the strength of the radiation field in the Clouds, dust properties and a discussion about the gas-to-dust ratio. Section 3 gives relations between the infrared and dust properties derived on global scales and for local areas, and their implications for other galaxies. Because the Magellanic Clouds are part of the Local Group of galaxies, we compared the infrared properties with those of the larger Local Group spiral galaxies in Section 4 and also with other irregular and spiral galaxies, with emphasis on the degree to which the Magellanic Clouds are representative for these types of galaxies.

#### 2. Infrared characteristics of the Magellanic Clouds

Before we discuss the Magellanic Clouds, we summarize the main characteristics of the Galactic foreground dust towards the Clouds.

##### 2.1. Galactic foreground dust

Using HI observations, we showed that on scales of  $15'$  there is little variation in the foreground dust towards the SMC. The extinction caused by the foreground is  $E_{B-V} = 0.08$  mag. This is twice that quoted by Koornneef (1984; and references therein), although Koornneef left open the possibility of large variations (0.01 – 0.07 mag). Thus, a large fraction of the observed reddening of SMC stars can be accounted for by foreground dust.

Towards the LMC, a significant variation in foreground reddening was found of 0.07 – 0.17, with an average of 0.10 mag. Towards this galaxy Koornneef (1984) gives a value of  $0.07 \pm 0.04$ . On average, our value is 40 % higher. Towards the LMC, the lowest reddening values are found for the Bar and the 30 Doradus region; the highest reddening values occur in the South region, where foreground filaments are observed by IRAS at infrared wavelengths.

The conversion from HI column densities to colour excess is done with the relation of Savage and Mathis (1979; and references therein). We showed that reddening values of McNamara and Feltz (1980) of 0.03 mag towards the LMC and 0.02 mag towards the SMC can only be obtained for values of  $N_{\text{HI}}/E_{B-V}$  3 to 4 times larger than the value adopted by Savage and Mathis, which corresponds to that of dense clouds such as the  $\rho$  Oph cloud. This value is unrealistically high and the interpretation of a larger foreground extinction is more likely. Visual and ultraviolet studies of the Clouds must be corrected for a higher and varying Galactic foreground. We do not exclude the possibility of more extreme foreground variations in  $E_{B-V}$  on smaller spatial scales ( $< 30'$ ).

## 2.2. Global infrared properties

In Table 1 we summarize the global infrared properties as derived in this thesis. The two Clouds have similar infrared spectra, characteristic of warm dust with typical temperatures of 33 K; although the spectra differ somewhat between 25 and 60  $\mu\text{m}$ . The SMC is 10 times weaker than the LMC at 60 and 100  $\mu\text{m}$  and 20 times weaker at 12 and 25  $\mu\text{m}$ . The infrared diameter of the LMC is 3 times larger than that of the SMC, and this can account for the most of the difference in far-infrared flux densities.

That the SMC has the same dust temperature as the LMC may look strange at first. The LMC is presently forming more stars per unit mass (Lequeux, 1984), and hence higher dust temperatures are expected. But for the SMC one must consider the effect that the stellar Bar occupies the whole galaxy with the exception of the Shapley Wing. The infrared observations show that the stars in the SMC-Bar are able to produce similar radiation fields as are found in the LMC. The Bar of the LMC only represents a fraction of the whole LMC. There we see an increase in dust temperature, against a cooler background; this shows the influence of the radiation field in areas with high stellar densities.

Table 1. Integrated Magellanic Clouds infrared data.

Quantity	Unit	LMC	SMC
Infrared area	( $^{\circ}$ ) <sup>2</sup>	34.0	2.4
Foreground $E_{B-V}$ mag		0.07 – 0.17	0.08
$f_{12\mu\text{m}}$	Jy	4850	147
$f_{25\mu\text{m}}$	Jy	11300	385
$f_{60\mu\text{m}}$	Jy	103000	7170
$f_{100\mu\text{m}}$	Jy	208000	13900
$T_{12-25\mu\text{m}}$	K	240	240
$T_{25-60\mu\text{m}}$	K	73	63
$T_d$	K	33	33
ISRF (IR)	$J_{\odot}$	7	7
ISRF (UV)	$J_{\odot}$	1	3
ISRF Intrinsic	$J_{\odot}$	8	10
$L_{\text{IR tot}}$	$L_{\odot}$	$9 \times 10^8$	$8 \times 10^7$
$L_{\text{IR}}/M_{\text{gas}}$	$L_{\odot}/M_{\odot}$	1.3	0.12
$M_d$	$M_{\odot}$	$5.5 \times 10^5$	$2.4 \times 10^4$

**Figure 1.** Total infrared luminosity and luminosity-to-mass ratio for the LMC.

Fig. 1.1 shows the total infrared luminosity at a resolution of  $8'$ . Grey scales range from 0 to  $10^{13} L_{\odot}/\text{sr}$ , darker grey scales indicating higher luminosities. Contours are at 20, 50, 100, 200, 500, 1000, 5000,  $10000 \times 10^9 L_{\odot}/\text{sr}$  ( $10^9 L_{\odot}/\text{sr} = 0.36 L_{\odot}/\text{sr}$ ).

Fig. 1.2 shows the infrared luminosity-to-HI mass at a resolution of  $15'$ . Grey scales range from 0 to  $56 L_{\odot}/M_{\odot}$ , darker grey scales represent higher ratios. Contours are at 2, 5, 10, 20,  $40 L_{\odot}/M_{\odot}$ .

**Figure 2.** Total infrared luminosity and luminosity-to-mass ratio for the SMC.

Fig. 2.1 shows the total infrared luminosity at a resolution of 8'. Grey scales range from 0 to  $5 \times 10^{11} L_{\odot}/\text{sr}$ , darker grey scales indicating higher luminosities. Contours are at 10, 20, 50, 100, 200,  $400 \times 10^9 L_{\odot}/\text{sr}$  ( $10^9 L_{\odot}/\text{sr} = 0.25 L_{\odot}/\text{sr}$ ).

Fig. 2.2 shows the infrared luminosity-to-HI mass at a resolution of 15'. Grey scales range from 0 to  $1.7 L_{\odot}/M_{\odot}$ , darker grey scales represent higher ratios. Contours are at 0.1, 0.2, 0.4, 0.6, 0.8,  $1.0 L_{\odot}/M_{\odot}$ .

### 2.3. The radiation fields in the Magellanic Clouds

The intrinsic ultraviolet radiation fields in the Clouds are 8 (LMC) and 10 (SMC) times stronger than the Solar Neighbourhood radiation field (Chapter V). These fields are two times stronger than derived by Vangioni-Flam *et al.* (1980), and show that their extinction corrections underestimate the emitted ultraviolet radiation. Therefore heating of dust is more efficient; it appears that 90 % (LMC) and 70 % (SMC) of the emitted ultraviolet emission is converted to infrared emission by dust. The higher fraction for the LMC is related to the higher dust content (see below). Because the average temperature of the dust is similar in the two galaxies, ultraviolet radiation is more efficiently absorbed by the higher dust content in the LMC, and in effect does not cause a significantly higher dust temperature in the SMC.

In Fig. 1 we show the distribution of infrared luminosity  $L_{IR}$  in the LMC, together with the luminosity-mass ratio map  $L_{IR}/M_{HI}$ ; Fig. 2 shows the same for the SMC. In general the latter figures represent infrared activity per unit of HI mass. If all dust would emit at the same temperature, the luminosity-mass relation would be a scaled dust-to-gas ratio, and its distribution would show variations of the dust-to-gas ratio. If, on the other hand, we would assume a constant dust-to-gas ratio in the Clouds,  $L_{IR}/M_{HI}$  represents a temperature-to-mass ratio, indicating the strength of the radiation field. In general a combination of these two effects is expected. The infrared emission dominates the total luminosity of the galaxies while the HI mass contains a large fraction (10 – 30 %) of the total mass. The ratio  $L_{IR}/M_{HI}$  can be used as a luminosity-to-mass ratio for these galaxies.

### 2.4. Dust properties

Infrared emission at 60 and 100  $\mu\text{m}$  is emitted by large dust grains (see Hildebrand, 1983). In Local Group spiral galaxies this type of dust is associated with atomic hydrogen (Cox *et al.*, 1988; Walterbos and Schwing, 1987; Rice *et al.*, 1988a). In spiral galaxies of the Virgo cluster, Leggett *et al.* (1986) have suggested dust to be associated with molecular gas and not with HI. Although  $\text{H}_2$  and CO may be related in a different way in the Clouds than in the Galaxy, the absence of large amounts of carbon monoxide in the Clouds (Cohen *et al.*, 1988) and the relatively high atomic hydrogen content suggest a correlation with HI. As in general LMC maps of HI and CO correlate both with infrared emission, we cannot decide from these maps, which of these components is associated with the dust. In the SMC, little CO is observed (Rubio *et al.*, 1984), and this also shows some evidence for a relation of dust with HI.

Polycyclic Aromatic Hydrocarbons are thought to be responsible for the mid-infrared (12 and 25  $\mu\text{m}$ ) emission. For the SMC we calculate that other constituents contribute at most 50 % of the mid-infrared emission, this may in fact be a large overestimate. Empirically (by allowing the emissivity exponent to vary) we find that about 25 % of the 25  $\mu\text{m}$  emission should be related to the PAHs, and about 90 % of the 12  $\mu\text{m}$  emission. The observed mid-infrared excess emission of the Clouds is much smaller than in the nearby spiral galaxies (M31, M33) and the Milky Way. As a consequence, the 60  $\mu\text{m}$  emission of the Clouds contains a much smaller contribution by these small grains than in the case of the spirals. For the Galactic foreground we calculated a possible contribution of 40 % (Chapter IV). Using the Clouds global characteristics we find 60  $\mu\text{m}$  PAH contributions of

17 % (LMC) and 8 % (SMC). The mass of *all* the dust is found to be  $(5.5 \pm 2) \times 10^5 M_{\odot}$  for the LMC and  $(2.4^{+2.2}_{-0.2}) \times 10^4 M_{\odot}$  for the SMC. An estimate for the fraction of cold (15 K) dust associated with molecular hydrogen is 20 % (LMC) resp. 30 % (SMC) of the total dust mass. From Table 1 we see that there appears to be no dust in the SMC with temperatures between 23 K (typical for Solar Neighbourhood dust) and 28 K; this results in the relatively large uncertainty. The mass of the hot ( $\sim 300$  K) dust that emits at 12 and  $25 \mu\text{m}$  is only a few solar masses and is negligible compared to the cool dust mass.

### 2.5. The gas-to-dust ratio

Several authors have investigated the gas-to-dust ratios in the Magellanic Clouds. Instead of the total gas column density, the column density of atomic hydrogen is used and the ratio  $N_{\text{HI}}/E_{B-V}$  is derived. Neutral hydrogen column densities are taken from 21-cm radio line-radiation or 1216 Å Ly $\alpha$  absorption in line profiles, and visual extinction is obtained from measurements at B and V wavelengths, the Cepheid Period-Luminosity relationship or by galaxy counts. The ratios derived with these methods are compared with the average Galactic value (Bohlin *et al.*, 1978) of  $5 \times 10^{21}$  H-atoms  $\text{cm}^{-2} \text{mag}^{-1}$ . All of these studies show that the global gas-to-dust ratios in the Clouds are considerably larger than average Galactic values: approximately 4 (LMC; Koornneef, 1984) and 17 (SMC; Lequeux *et al.*, 1984) times. However, there is a large spread in gas-to-dust ratios derived from different observations. In Table 2 we summarize these observations.

**Table 2.** Gas-to-dust ratios relative to the Galactic value.

Object	Reference	$\frac{\text{gas}}{\text{dust}}$ <sup>a)</sup>	Measurements
SMC	van den Bergh (1968)	> 10	HI 21-cm; Cepheid P-L relation.
	van Genderen (1969)	5 – 12	HI 21-cm; Cepheid P-L relation.
	Dachs (1970)	> 100	HI 21-cm; photometry. <sup>b)</sup>
	Hodge (1974)	3	HI 21-cm; galaxy counts.
	MacGillivray (1975)	3	HI 21-cm; galaxy counts.

Note to Table 2:

- a)  $\frac{\text{gas}}{\text{dust}}$  is the ratio of the gas-to-dust ratio of each Cloud divided by that of the Milky Way.  
 b) These authors compare the extinction to the stars with the integrated line-of-sight HI emission; hence on average, half their values should be better.

In Chapter VI we derived dust masses for the Clouds from infrared thermal emission. From these masses we find global gas-to-dust mass ratios,  $M_{HI}/M_d$ , for the Clouds of  $980^{+560}_{-260}$  (LMC) and  $20000^{+2000}_{-10000}$  (SMC). For the LMC the ratio is  $3^{+3}_{-1}$  times higher than for the Galaxy and for the SMC  $55^{+25}_{-40}$  times higher. We have assumed an average Galactic gas-to-dust ratio of  $375^{+200}_{-100}$  by using the ratio of Chapter IV after correcting for the line-of-sight temperature decomposition (Chapter VI). Although this Galactic value is a few times higher than canonical values (Hildebrand, 1983), it was derived in a similar way as the dust mass of the Clouds and its use therefore greatly decreases the effect of systematical errors in the dust properties. We summarize different gas-to-dust ratios derived from various kinds of masses in Table 3.

We discuss our results in relation with the results of Lequeux *et al.* (1984) and Bouchet *et al.* (1985) for the SMC and Koornneef (1982) for the LMC, who all use direct line-of-sight measurements. From maps in Chapter VI we see variations in the gas-to-dust ratio over the face of each Cloud. For the LMC the derived global gas-to-dust ratio of 3 agrees very well with the average ratio of Koornneef (1982), while the errorbars are quite narrow. However, the average SMC ratio is 3 times larger than the value of Lequeux *et al.* (1984), and 6 times larger than the value derived by Bouchet *et al.* (1985). Our lower limit of 15, based on a possibly large amount of dust with temperatures of 23 – 28 K, is similar to their values. Note that to achieve this limit the lowest possible SMC gas-to-dust ratio was divided by the highest possible Galactic ratio.

**Table 3.** Mass-ratios in the Magellanic Clouds.

Quantity	LMC	SMC
Gas-to-dust ratios: <sup>a)</sup>		
$M_{HI}/M_d$	$980^{+560}_{-260}$	$20000^{+2000}_{-10000}$
$M_{gas}/M_d$	$1600^{+900}_{-400}$	$33000^{+3000}_{-16000}$
$M_{dyn}/M_d$	$11000^{+6000}_{-3000}$	$63000^{+5000}_{-30000}$
$M_{dyn}/M_{gas}$	7	2
Ratio Cloud/Milky Way: <sup>b)</sup>		
$M_{HI}/M_d$	$3^{+3}_{-1}$	$55^{+25}_{-40}$

Note to Table 3:

a) All mass ratios are dimensionless.

b) For the Milky Way we have used a gas-to-dust ratio of  $375^{+200}_{-100}$ .

The agreement for the gas-to-(infrared) dust ratio and the gas-to- $(E_{B-V})$  ratio of the LMC has several implications. First of all, it confirms the high gas-to-dust ratio, and shows that dust is not locked up in very large grains with low visual reddening. The two completely independent methods give similar results and their connection is well understood. The third implication is that there are no large amounts of cold (15 K) dust in the LMC (about 20 % of the total dust mass), and that the dust mass is dominated by cool (25 K) dust. The strong average radiation field in the LMC has a destructive influence on molecular clouds, and heats their dust to higher average temperatures. Using the cool and cold components we extrapolate the observed IRAS integrated LMC 100  $\mu\text{m}$  flux densities to 35 kJy at 300  $\mu\text{m}$  (3 % by cold dust) and 1 kJy at 1-mm (8 % by cold dust).

Why then is the SMC gas-to-dust ratio that we derived so much higher than the value of Lequeux *et al.* (1984) and Bouchet *et al.* (1985) ? Let us assume that the value derived for the SMC dust mass is too small. We note that the calibration of the infrared maps are correct (Chapter V). To obtain agreement with Lequeux *et al.* (1984) three times more dust should be present. This can be achieved by adding cold (15 K) dust. The presence of such large amounts of cold dust can be confirmed directly from observations at sub-mm wavelengths and indirectly by measurements of molecular complexes. If we have three times more cold dust than cool dust, it will not influence the 100  $\mu\text{m}$  flux density but the flux density at 300  $\mu\text{m}$  would be  $\sim 3400$  Jy instead of 2600 Jy, and 120 Jy at 1 mm instead of 75 Jy without the cold dust. Lacking actual measurements we nevertheless believe that large amounts of cold dust in the SMC are improbable in view of the Milky Way's ratio of cold and cool dust (Cox and Mezger, 1988). The Clouds are young galaxies with low metallicities and a low molecular content, and we therefore, in fact, expect relatively less cold dust than in the Galaxy. The small amount of cold dust that can be added in the LMC is in agreement with this. A more likely possibility is more dust of about 25 K. The line-of-sight decomposition in the SMC shows only a small increase in dust mass because the lowest temperatures are 28 K. If there is 3 times more dust of 25 K, it is strange that there are no regions dominated by purely cool (25 K) dust. It is possible that such a dust component is mainly present in the line-of-sight. Mathewson *et al.* (1986) has observed stars in a long line-of-sight in the SMC SW-Bar; this line-of-sight is non-uniformly filled and observations of the farthest star in this region (*e.g.* HV 1369; van Genderen, 1981) do not show a large increase in  $E_{B-V}$ . But the contribution of more cool dust in the line-of-sight cannot be excluded. If this is the case, we may apply the LMC temperature decomposition (Chapter VI) on the SMC dust mass. An addition of a factor of three in 25 K dust would take up 40 % of the observed 100  $\mu\text{m}$  flux density and dominate the prediction at 300  $\mu\text{m}$  ( $\sim 3600$  Jy) and 1-mm ( $\sim 110$  Jy). The large contribution to the observed 100  $\mu\text{m}$  flux densities would increase the average temperature of the cool/warm component from 33 K to 43 K. The changes that are needed in order to add enough cool (25 K) or cold (15 K) dust are too large to seem possible.

As a check, we have compared the SMC ratio with gas-to-dust ratios derived for other (dwarf) irregular galaxies. We used integrated data of Hunter *et al.* (1986) and Rice *et al.* (1988b) and found ratios for DDO 47 and DDO 50 even higher than the SMC gas-to-dust ratio based on integrated data. All irregulars have ratios  $L_{100\mu\text{m}}/M_{\text{HI}}$  comparable to that of the SMC, and after temperature correction they have similar gas-to-dust ratios.

Hence the high gas-to-dust ratio in irregular galaxies compared to spirals is probably real. (See also the discussion in Section 4).

Let us consider the other possibility, that  $E_{B-V}$  derived by Lequeux *et al.* (1984) and by Bouchet *et al.* (1985) is too high, or that their Ly $\alpha$  profiles underestimate the HI column densities. To explore this possibility, we discuss the difficulties inherent in the determination of  $E_{B-V}$ . Observed HI column densities are on average  $15 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$  for the LMC,  $45 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$  for the SMC and only  $5 \times 10^{20}$  H-atoms  $\text{cm}^{-2}$  for the Galactic foreground; this shows that the SMC HI dominates the foreground emission. A variation of Galactic foreground on small spatial scales will produce larger errors and complicate the analysis of the gas-to-dust ratio. On large scales the SMC foreground is rather smooth (Chapter IV), but local variations cannot be excluded. (In the area of SN 1987A in the LMC, variations of 0.04 to 0.16 mag in foreground were found on a scale of  $10'$ ; Goudfrooij, priv. comm.). The foreground  $E_{B-V}$  derived towards the SMC in Chapter IV ( $E_{B-V} = 0.08$  mag) is a factor of 2 higher than normally assumed for the foreground (Koornneef, 1984). This suggests that most of the observed extinction ( $E_{B-V} = 0.10 - 0.15$ ) is associated with foreground material. The derived ratios  $N_{\text{HI}}/E_{B-V}$  are therefore closer to Galactic values than those taking into account the higher foreground. Towards the LMC the effect is less, as foreground reddening values differ only by 40 % and the internal LMC extinction is higher. A third possibility that complicates the analysis is spectral misclassification (*e.g.* binary stars), which leads to erroneous values of  $E_{B-V}$ .

**Figure 3.** Relation between  $N_{\text{HI}}$  and  $E_{B-V}$  for the SMC.

The data are from Bouchet *et al.* (1985). The dotted line shows the Galactic gas-to-dust ratio, the dashed-dotted line shows the ratio derived by Bouchet *et al.* (1985) using the filled squares, except the two with the highest reddening. The dashed line give our refit of the data assuming large foreground variations for the two points with low reddening. See Bouchet *et al.* (1985) for more details.

We have re-evaluated the data of Bouchet *et al.* (1985). In their derivation the stars AV 214 and AV 398 were not included due to large reddening ( $> 0.27$  mag) and the possibility of having  $H_2$  in the line-of-sight. We also exclude these stars, which are located in the NE-Bar. In view of the large foreground we expect also relatively large errors for stars with  $E_{B-V} < 0.05$  mag. In addition, we therefore ignore the two stars with exceptionally low reddening (Sk 94 and Sk 145). Foreground fluctuations at small scales are likely the cause of the extremely small or large observed reddenings. We then find a reasonably good correlation between the remaining data points, and a steep fit crossing the  $E_{B-V}$ -axis roughly at the foreground reddening of Chapter IV, but the uncertainties mentioned above also apply to these data points. We find a formal fit  $N_{HI}/(E_{B-V} - 0.09) = 20 \times 10^{22}$  H-atoms  $cm^{-2}/mag$ , 40 times higher than the average Galactic gas-to-dust ratio. This value is in good agreement with the ratio  $M_{HI}/M_d$ , derived from the dust and HI masses. Because of the steep slope the actual value of  $N_{HI}/E_{B-V}$  has a high uncertainty. Fig. 3 shows the relations between  $N_{HI}$  and  $E_{B-V}$  derived from the data of Bouchet *et al.* (1985).

Only a few tens of supergiant stars have been studied, while the dust contents of the Clouds are low. To derive accurate values for  $E_{B-V}$ , lines-of-sight must be studied with relatively high dust contents, which therefore select lower gas-to-dust ratios, *e.g.* by using stars that are farther away than the average distance, or with extra foreground dust. This might result in biased extinction values, and hence in gas-to-dust ratios which are too small.

There is another problem. Is  $N_{HI}/E_{B-V}$  the same gas-to-dust ratio as  $M_{HI}/M_d$ ? If this is the case, we determine similar quantities. The relation between these quantities can be found from

$$A_V = R E_{B-V} = 1.086 \tau_V = 1.086 \pi a^2 Q_V^{ext} N_d; \quad (1)$$

hence there is a linear relation between the two:

$$N_{HI}/E_{B-V} = R/(1.086 \pi a^2 Q_V^{ext}) \left( \frac{4}{3} \pi a^3 \rho_d / m_{HI} \right) (M_{HI}/M_d) \quad (2)$$

(here  $m_{HI}$  represents the mass of a hydrogen atom,  $a$  and  $\rho_d$  resp. the average radius and density of grains;  $Q_V^{ext}$  is the visual extinction efficiency factor;  $R$  is the ratio of total to selective extinction). Therefore, if average values of  $R$ ,  $a$ ,  $\rho_d$  or  $Q_V^{ext}$  are not the same in the Clouds as in the Galaxy, a different relation between the two measures of the gas-to-dust ratio exist.

Differences in the ultraviolet part of the extinction curve of the SMC, the LMC and the Galaxy show that the dust particle size distribution of the SMC has a steeper rise for small grains than the LMC and the Galaxy. Hence  $a$  might be smaller. It also suggests  $R \approx 2$ . Isserstedt (1976, 1980) has observed that  $R = 2$  in the SMC; later Stift (1984) found a value for  $R$  in the SMC considerably larger than the Galactic value of 3.1. Bouchet *et al.* (1985) have derived a value of  $R = 2.7 \pm 0.2$  in the SMC, very near the Galactic value. These differences clearly show the uncertainties involved in determinations of  $R$ . To explain the difference in gas-to-dust determined from  $E_{B-V}$  and from infrared emission

purely by dust property differences, the factor  $R \propto \rho_d / Q_V^{\text{ext}}$  must be 3 – 6 times smaller in the SMC than in the Milky Way. There are not enough data available to further discuss this possibility. The observed agreement for the LMC and the Galaxy may indicate that at least there this factor is not that large.

To summarize the gas-to-dust ratio, we have shown that the LMC ratio derived from infrared measurements, agrees with that based on recent measurements using  $E_{B-V}$ . For the SMC a discrepancy between  $M_{\text{HI}}/M_d$  and  $N_{\text{HI}}/E_{B-V}$  exists of a factor 3 – 6. This can be explained in several ways. First of all, large amounts of dust with temperatures between 23 and 28 K could be present, in lines-of-sight with large amounts of dust with higher temperatures. Second, the connection between  $E_{B-V}$  and  $M_d$  does not have to be similar to that in the Galaxy. Thirdly, the Galactic foreground is probably more important than commonly assumed in the analysis of reddening values. We have shown that the last option is the most probable one. We have re-analysed the data of Bouchet *et al.* (1985) and found that a good agreement can be obtained between their data and our gas-to-dust ratio by using the higher Galactic foreground reddening. From now on we will use gas-to-dust ratios (relative to the Galactic value) of 3 in the LMC and 50 in the SMC.

In the SMC ~70 % of the ultraviolet emission is absorbed by dust. In the LMC this fraction is ~90 %. These fractions seem to be related to the amount of dust in these objects. Relative to HI, the LMC contains 15 times more dust. It is obvious that ultraviolet photons will have more difficulty leaving the LMC than the SMC. If we assume the same thickness for the Clouds, their diameters of 7.8 kpc (LMC) and 2.6 kpc (SMC) indicate a factor of 9 in volume. The dust density is 2.5 times higher in the LMC than in the SMC, but it only accounts for a relatively small increase in ultraviolet absorption.

Why is there an underabundance of dust in the Magellanic Clouds ? The Clouds are young irregular galaxies, with high relative gas contents (see *e.g.* Israel, 1984). In the SMC 30 % of the total mass consists of HI, in the LMC 10 %, while the Milky Way Galaxy only contains 1 % of its mass in the form of atomic hydrogen. If similar equilibrium conditions would occur in the Clouds as in the Milky Way, large amounts of  $\text{H}_2$  might be expected. On the other hand, the large amount of HI could also exclude large molecular gas abundances as  $\text{H}_2$  would never have formed from HI. Formation of  $\text{H}_2$  is done on grain surfaces. The lack of grains will then produce a lower abundance of  $\text{H}_2$ . CO is shielded from the interstellar radiation field by grains, which protect CO against dissociation. CO observations of the LMC (Cohen *et al.*, 1988) reveal a molecular underabundance. In the SMC this underabundance is even more extreme.

From the work of Koornneef (1982) and Bouchet *et al.* (1985) it seems that the dust-to-gas ratio is directly proportional to the metallicity. From Dufour (1984) we know that the abundance of oxygen is 2 times less in the LMC compared to the Solar Neighbourhood, and in the SMC it is 5 times less. For carbon the underabundance is 4 times in the LMC and 30 times in the SMC, compared to the Solar Neighbourhood. Hence the observed gas-to-dust ratios in the LMC and in the SMC go approximately linear with the abundance of carbon and roughly squared with the abundance of oxygen.

### 3. The relation between global and local characteristics

Studies of distant galaxies are hampered by low linear resolution. Distant objects are therefore seen as point sources, or marginally resolved; this is especially true for data of the IRAS satellite which had resolutions larger than  $1' \times 5'$ . In our Galaxy, the opposite is true: local phenomena can be studied but we cannot see the forest for the trees. The Magellanic Clouds offer a unique opportunity to study both, galactic structure in detail as well as global properties.

There are two possibilities to achieve spatial resolutions. Firstly, there is spatial resolution in the sky plane (by high instrumental resolutions). Secondly, we can do some kind of modelling to resolve lines-of-sight. The following basic quantities, important in infrared analysis, are influenced by resolution effects.

Temperatures will be biased towards the highest values in the observing beam; thus properties derived from it will be biased (dust masses will be underestimated, extrapolated luminosities will be overestimated). In Chapter VI we have used a method to decompose lines-of-sight in galaxies into various temperature components.

From the Clouds' integrated data we can predict dust masses of other galaxies. The integrated data give rise to a dust temperature  $T_d$ , and a dust mass  $M_d$ . We assume that cool and warm dust are both present, with temperatures of above  $\sim 23$  K. From the LMC data we find that spatially resolving the galaxy to about 120 pc increases the mass by a factor of 1.4, while the line-of-sight temperature decomposition increases the mass by another factor of 2. If the coolest dust present has a temperature not much lower than  $T_d$  we have the SMC case. Then the decomposition will increase the dust mass by only 20 %.

The mass of cold (15 K) dust in the Clouds can be extrapolated to other irregular galaxies. From the mass of cool ( $\sim 23$  K) dust based on integrated data ( $M_d$  above) this cold dust mass can be found accurately as  $(0.6 \pm 0.3) \times M_d$ .

Helou's (1986) colour-colour diagram shows a relation between IRAS data  $f_{12\mu m}/f_{25\mu m}$  and  $f_{60\mu m}/f_{100\mu m}$  for integrated data of galaxies. The integrated flux densities of the Clouds also follow the curve for these galaxies. In Chapter V we showed that the Clouds' ratio maps also show the same relation. Individual areas of the Clouds show the same characteristics as the integrated data of all galaxies. Hence for other galaxies we expect the same to be true: individual areas must occupy a part of the relation in the diagram.

### 4. The Magellanic Clouds compared to other galaxies

#### 4.1. Local Group spiral galaxies

The Local Group consists of about thirty galaxies, of which the largest spirals are the Milky Way Galaxy, M31 and M33. Integrated infrared data for these galaxies has been taken from Cox *et al.* (1986), Cox and Mezger (1988), Walterbos and Schwing (1987) and Rice *et al.* (1988a). For comparison reasons we have added a few well known spiral galaxies: IC342, M51, M81 and M101 (Rice *et al.*, 1988b). Although the sample is small, we try to find systematic similarities and differences between the Clouds and these spiral type galaxies from the infrared data.

We show the relation between the independent colours  $f_{12\mu m}/f_{25\mu m}$  and  $f_{60\mu m}/f_{100\mu m}$  for these galaxies in Fig. 4. The Magellanic Clouds are added as well as some other

irregulars (see Section 4.2). The spirals are all at the lower right end of the diagram. Note the two very different positions of the Milky Way in the diagram (MWG1 is based on pre-IRAS data, MWG2 on post-IRAS data). The point marked X corresponds to infrared colours of cirrus dust; the point marked Y to infrared colours of dust in strong radiation fields. We see that the Clouds are to the left of the spirals, indicating stronger radiation fields. Together with the higher  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$ ,  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  is lower in the Clouds than in the Local Group spirals. Except for MWG2 and NGC 1569, the galaxies are in the area of integrated galaxy colours of Helou (1986).

**Figure 4.** IRAS infrared colour-colour diagram.

The flux densities used for the colours are in Jy. Spirals are indicated by crosses while irregulars are indicated by open squares, the Clouds by filled squares. The points X and Y have infrared colours of cirrus dust and dust present in strong radiation fields resp. The galaxy names are used as labels. The galaxy area of Helou (1986) is indicated by the dashed area. Note that only galaxies with good infrared flux densities in four bands are shown.

**Figure 5.** Relation  $L_{100\mu m}/M_{HI}$  with  $f_{60\mu m}/f_{100\mu m}$ .

We used  $L_{100\mu m}/L_{\odot}$  and  $M_{HI}/M_{\odot}$  and the IRAS flux densities in Jy. Points X and Y are the same as in Fig. 4 (arbitrary scaled). Spirals are shown by crosses, irregulars by squares and the Clouds by filled squares. The galaxy names are used as labels. Lines parallel to the dashed line give the behaviour of galaxies with constant dust-to-gas ratio with temperature. Together with the band ratios, the dust temperature derived from this ratio are given above the diagram for  $\epsilon_{\nu} \propto \nu^{1.5}$ .

The integrated infrared properties of the Clouds are remarkably different from those of the spirals. Spectral differences are expressed in their band ratios as shown in Fig. 4. Although  $f_{25\mu m}/f_{60\mu m}$  are very similar ( $\sim 0.1$ ) for these galaxies (only M31 and MWG2 are different with  $\sim 0.25$ ), clear differences occur between 12 and 25  $\mu m$  and between 60

and  $100\ \mu\text{m}$ . These spectral differences must be interpreted as follows. The small grains (PAH) cirrus emission in the spirals is larger than in the Clouds, which is probably related to the higher metallicity in these galaxies. Hence the contribution of PAHs at the  $60\ \mu\text{m}$  emission is also larger than in the Clouds, and physical dust temperatures are smaller than predicted from the ratio  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$ . For the Clouds the contribution of PAHs at  $60\ \mu\text{m}$  is 17 % (LMC) resp. 8 % (SMC); in M31 it is probably higher (Walterbos and Schwoering, 1987). Dust temperatures in the Clouds are higher than in the spirals. In Chapter VI we listed the infrared luminosities of the Local Group galaxies; their values correlate with the size of the objects and are therefore not clearly related to the galaxy type.

The Clouds have low dust abundances, hence smaller optical depths at ultraviolet wavelengths. These young galaxies, especially the LMC, are presently in a phase of star formation. Their ultraviolet radiation field is stronger than the average Galactic field. Combining these effects, the average dust grain can be heated to higher temperatures than in the spirals. The smaller size of the Clouds will make it easier for the field to heat all dust present.

The lower dust temperature of the spiral galaxies will make mass estimates easier for the cool (25 K) component. However the spirals contain larger amounts of cold (15 K) dust. Data presented by Cox and Mezger (1988) suggests a similar gas-to-dust ratio for the molecular and atomic components.

From the diagram of  $L_{IR}/L_B$  versus  $f_{100\mu\text{m}}/f_{60\mu\text{m}}$  of Caspers (1987), we compare the Clouds with M31 and M33. Again both spirals are shown to be cooler than the Magellanic Clouds. But,  $L_{IR}/L_B$  of the Clouds and M33 are very similar, while that of M31 is about 7 times smaller. This can be accounted for by the activity of the Clouds and M33 compared to M31.

The relation between the gas-to-dust ratio in the Clouds and the spiral galaxies is shown in Fig. 5. We show  $L_{100\mu\text{m}}/M_{HI}$  as a function of  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$ . Lines parallel to the dashed line indicate a constant gas-to-dust ratios over the range of  $f_{60}/f_{100}$ . Vertical displacements at a single ratio  $f_{60}/f_{100}$ , represent differences in dust-to-gas ratio. Most spirals are above the line, showing high dust-to-gas ratios. From the figure we see that the dust-to-gas ratio of the LMC is somewhat lower than that of average spirals. The differences between the LMC and the Milky Way (a ratio of 3), and between the SMC and the Milky Way (a ratio of 30) agree with the differences in gas-to-dust ratio derived in Section 2. The diagram of Fig. 5 provides a simple but powerful tool for estimating relative dust-to-gas ratios in galaxies. It predicts dust-to-gas ratios in M31 and M33 two times less than in the Milky Way and in M51 and M81 about 2 times higher. For M101 and IC342 the ratios are somewhat lower than for the LMC. These dust-to-gas ratios agree at least qualitatively with the oxygen abundance determinations for the Clouds and some spiral galaxies (*cf.* Pagel and Edmunds, 1981). M31 does not fit in this picture, its weak infrared emission compared to  $M_{HI}$  and compared to  $L_B$  (see above) combined with the low dust temperature, are the main reasons for the low derived dust-to-gas ratio of this early type spiral. If a large fraction of the  $60\ \mu\text{m}$  emission of this galaxy is related to very small grains, the average grain temperature will be smaller and the galaxy moves to the right in the diagram.

#### 4.2. Irregular galaxies

The Clouds are irregular galaxies. In addition to the data of spirals, Fig. 4 also shows data of some (dwarf) irregular galaxies. These data are from Hunter *et al.* (1986), Rice *et al.* (1988b) and Israel (1988). The HII/blue compact galaxy II Zw 40, NGC 1569 and NGC 6822 are located close to point Y, reflecting their present high star formation activity. NGC 1569 and 6822 have similar ratios  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  as those of the other irregular galaxies, but the large discrepancy for  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  causes the very different positions. The weakness at  $12\mu\text{m}$  for these galaxies, related to a low content of small grains, can account for their location. The other irregulars, DDO 50, NGC 4449, NGC 4656 are at the same position in the diagram as the Clouds. Their ratio  $f_{25\mu\text{m}}/f_{60\mu\text{m}}$  are also very similar. All irregular and Magellanic type galaxies in the list of Rice *et al.* (1988b) have been used. Only those with good flux densities in all four IRAS bands have been plotted. Of the other five, three have similar  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  ratios. This makes the difference between the Clouds and the spirals even more intriguing. All irregular galaxies show similar colour differences with the spirals.

The positional differences between the irregulars and the Clouds must be interpreted in terms of stellar activity and small grain content. More active galaxies are to the upper-left of the diagram. Because irregulars are more active than spirals, they are to the left of spirals. We have only a limited sample of galaxies, which should make us careful in extrapolating results to a complete sample of galaxies. We have observed the brightest irregulars, and so selected the closest and most active systems. The same is true for the spirals, except their larger size will make them easier visible.

Because of their position among the irregular galaxies, the Magellanic Clouds are representative of the sample of irregulars, and can be used to derive properties in these galaxies. The agreement is especially good for the ratio  $f_{60}/f_{100}$ . Differences in  $f_{12}/f_{25}$  must be explained by differences in the small grain contents. Especially the temperature distribution in the Clouds can be used to perform the line-of-sight decomposition to find total dust masses.

Caspers (1987) showed a diagram of  $L_{\text{IR}}/L_{\text{B}}$  versus  $f_{100\mu\text{m}}/f_{60\mu\text{m}}$  for a sample of nearby dwarf irregular galaxies and a sample of blue compact galaxies. In the diagram he added our Magellanic Cloud data, together with some other well known galaxies. We restrict ourselves to a comparison with the dwarf irregulars. The SMC is just in the middle of the sample. Its diameter of 2.6 kpc makes it a typical dwarf irregular galaxy. The LMC is larger (7.8 kpc diameter), and has a high ratio  $L_{\text{IR}}/L_{\text{B}}$  compared to the average value for the dwarf sample; some higher values occur (*e.g.* NGC 1569). The dust temperature of both Clouds is well within the range of the dwarf sample. The effect of removal of dust in galaxies on the diagram is explained by the Caspers. Because  $L_{\text{IR}}$  is directly proportional to the dust mass it will go down. Due to the lower number of absorbers,  $L_{\text{B}}$  goes up. With the same radiation field and less absorbers, the average number of photons impacting on each dust particle is larger and the equilibrium temperature will be higher. The effect is that galaxies move in the diagram to the lower-right. A similar scenario for a burst of star formation can be set up; it will lead to galaxy movements to the upper-right.

In Fig. 5 we show the relation between  $L_{100\mu\text{m}}/M_{\text{HI}}$  and  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  for the irregular galaxies and the Clouds, together with the spirals. Again we note the difference between NGC 1569 and II Zw 40 with the other irregulars (*cf.* the irregular galaxy NGC 6822).

The position of the SMC is in the middle of the sample of irregulars, showing that the dust content of the SMC is in agreement with that of the other irregulars. The relatively high positions of the LMC and NGC 4449 is the result of their higher dust-to-gas ratios. We see that the SMC is a good representative of the sample of irregulars, but the LMC is an extreme case. The oxygen abundance of the LMC, the SMC, NGC 4449, NGC 6822 and II Zw 40 (Chiosi and Matteucci, 1984) are qualitatively in agreement with the positions of these galaxies in the diagram. From the figure we see that the galaxies with higher abundances (LMC, NGC 4449) have the highest dust-to-gas ratios.

### Acknowledgements

I want to thank Drs. A. van Genderen and P. Goudfrooij for useful discussions.

## Appendix

### ON THE INTERPRETATION OF IRAS INFRARED OBSERVATIONS

#### 1. Introduction

For the interpretation of IRAS infrared data it is important to understand the nature of the infrared emission. This appendix gives an overview of the basic physical principles, astronomical ideas and objects that are responsible for the infrared radiation emitted by galaxies, as well as equations, tables and figures of use in obtaining physically relevant parameters from the observed infrared data.

Interpretation of the infrared observations by IRAS is complicated by the fact that the wavelength bands were not infinitely small and by the fact that we are dealing with various physical dust components in the line-of-sight. Other important considerations are resolutions of the different wavelength bands (which, for comparison reasons, should be identical) and calibration and noise effects.

Physically relevant parameters that can be derived from the infrared data are described in this appendix, these are dust temperature  $T_d$ , infrared luminosity  $L_{IR}$ , dust column densities  $N_d$ , dust masses  $M_d$  and dust-to-gas ratios  $M_d/M_{HI}$ .

#### 2. Mechanisms and origin of infrared radiation

##### 2.1. Mechanisms of infrared radiation

Line, band and continuum emission contribute to observed infrared radiation. Line emission is detected in ground based observations with high spectral resolution (*e.g.* Continuous Variable Filter, CVF; Cooled Grating Spectrometer, CGS). In the near-infrared (NIR:  $1\ \mu\text{m} < \lambda < 10\ \mu\text{m}$ ) line emission has been found from various atoms (*e.g.* H: Br $\alpha$ , Pf $\alpha$ ), ions (*e.g.* Ar III, S IV) and molecules (*e.g.* H<sub>2</sub>) (Harwit, 1982: general discussion; Watson, 1982: Orion nebula; Smith, 1982: galaxies; Lacy, 1982: HII regions; Israel and Koornneef, 1987: H<sub>2</sub> in Magellanic Cloud HII regions). Very small grains may be responsible for 12 and 25  $\mu\text{m}$  continuum radiation (Draine and Anderson, 1985). They are proposed to be Polycyclic Aromatic Hydrocarbons (PAHs), which also show line emission in the near-infrared (Léger and Puget, 1984); their existence explains some near-infrared emission features (Sellgren *et al.*, 1983). Line emission in the mid-infrared wavelength range (MIR:  $10\ \mu\text{m} < \lambda < 30\ \mu\text{m}$ ) is seen in IRAS Low Resolution Spectrometer observations (IRAS LRS, 1986). Spectral features are observed at infrared wavelengths, in emission and in absorption: *e.g.* the silicate features at 9.7 and 18  $\mu\text{m}$ , and various other features for  $\lambda < 10\ \mu\text{m}$  (Willner, 1982). Line emission in the far-infrared (FIR:  $30\ \mu\text{m} < \lambda < 250\ \mu\text{m}$ ) was proposed by Pottasch (1986) and by Leene and Pottasch (1986) for various planetary nebulae (*e.g.* S III, S IV, O III, O IV, Ne II and N III lines). They showed that these lines may contribute a large fraction of the observed IRAS flux densities.

In general, continuum infrared emission is split in thermal and non-thermal contributions. The non-thermal processes are Inverse Compton radiation and Synchrotron emission. The latter of these, which decreases rapidly with increasing wavelength, plays a role in those SNRs that have a flat radio spectrum, like Taurus A (Crab nebula; Marsden *et al.*, 1984). Hildebrand *et al.* (1977) and Jones and Stern (1975) have shown that these emission processes cannot be main contributors to far-infrared emission of galaxies. Thermal emission processes are free-bound emission and free-free (Brehmstrahlung); these were discussed by Waters (1986) in his interpretation of the infrared excess of four Be stars with circumstellar discs. Blackbody emission from stars (the Rayleigh-Jeans tail of the Planck function) is seen in nearby stars. For example a G2V star, such as the Sun, with a temperature of 5800 K, has its maximum energy emission of the Planck curve  $\nu B_\nu$  at  $0.6 \mu\text{m}$ ; at infrared wavelengths still 50 % of the maximum energy is left at  $1.25 \mu\text{m}$  (J-band) but only 0.2 % at  $10 \mu\text{m}$  (N-band). The most important emission mechanism is the modified blackbody emission of dust heated by an external heating source. This heating process is photo-heating (near ELD HII regions and in the general interstellar radiation field, ISRF; to which contribute the young and old stellar population) or shock-heating (possibly near supernova remnants or shell structures; see Braun, 1985; Dwek, 1988).

## 2.2. Origin and sources of infrared radiation

The principal heating sources of dust in the Galactic disk have been discussed by Cox *et al.* (1986) using pre-IRAS infrared observations. They propose the following dust components:

- (1) Cold dust ( $< T_C > \approx 14 \text{ K}$ ) associated with quiescent molecular clouds ( $\text{H}_2$ ), heated by the general ISRF, or at the outmost edges of galaxies.
- (2) Cool dust ( $T_C \approx 15 - 25 \text{ K}$ ) associated with atomic hydrogen (HI), heated by the general ISRF. In our Galaxy components (1) and (2) contain a luminosity of  $5.7 \times 10^9 L_\odot$ .
- (3) Warm dust ( $T_C \approx 30 - 40 \text{ K}$ ) associated with ionized gas in extended low density HII regions (ELD;  $n_e \gtrsim 10^2 \text{ cm}^{-3}$ ) and heated by O-stars; and with molecular gas in dense ( $2n_{\text{H}_2} \approx 10^3 \text{ cm}^{-3}$ ) shells surrounding B-stars. Its total luminosity in our Galaxy is  $\sim 7.6 \times 10^9 L_\odot$ .
- (4) Hot dust ( $T_C \approx 250 - 500 \text{ K}$ ) to which contribute in equal fractions very small grains (VSG; radius  $a \gtrsim 0.5 \text{ nm}$ ) in the form of PAHs heated by the ISRF, associated with the diffuse interstellar (HI) gas; and normal grains ( $a \gtrsim 0.1 \mu\text{m}$ ) heated by M-giants with heavy mass outflow (observationally known as OH/IR stars).

A renewed discussion of the infrared emission of the Galaxy based on IRAS data is given by Cox and Mezger (1988); they derived new luminosities somewhat different from the ones of Cox *et al.* (1986).

## 3. IRAS in-band intensities, specific intensities and colour corrections

The in-band intensity of IRAS wavelength band  $i$ , is the integration over the band of specific intensity convolved with the relative system response  $R_{i,\nu}$  (IRAS, 1985a; see Table

II.C.5 therein). In fact, the IRAS satellite measured in the  $i^{th}$  band:

$$I_i = \int_0^{\infty} d\nu R_{i,\nu} I_{\nu} \quad i = 12, 25, 60, 100 \text{ } \mu\text{m band.} \quad (3.1)$$

Specific intensities  $I_{\nu_i}$  are reconstructed from in-band intensities  $I_i$  by using bandwidth correction factors  $I_{\nu_i} = I_i / \Delta\nu_i$ . Because the IRAS photometric bands are rather wide compared to the wavelength ( $\Delta\lambda/\lambda \approx 0.3 - 0.6$ ) these factors depend on the intrinsic source spectrum. The IRAS flux densities in the catalogues and the specific intensities in the maps (IRAS, 1985a) assume a  $f_{\nu} = f_{\nu_i}(\nu/\nu_i)^{-1}$  intrinsic spectrum of the source or map pixel respectively; we call these  $f_{\nu_i}^{quoted}$ . The bandwidth correction factors for band  $i$  with nominal frequency  $\nu_i$  are found from

$$\Delta\nu_i = \int_0^{\infty} d\nu R_{i,\nu} (\nu/\nu_i)^{-1}. \quad (3.2)$$

These factors — given in Table 1 — are roughly correct for dust associated with HII regions, but not for *e.g.* stellar objects (which follow the Rayleigh–Jeans tail of the Planck function in the infrared; see Chapters II and III). To find the actual specific intensities the quoted values must be corrected for the intrinsic source spectrum:

$$f_{\nu_i}^{actual} = f_{\nu_i}^{quoted} / K_i. \quad (3.3)$$

These division factors  $K_i$  for a range of spectral powers are given in Table 2.A, and for modified blackbody spectra in Table 2.B. Their curves are displayed in Fig. 1. If the intrinsic source spectrum is unknown, the observed, quoted band ratios of adjacent bands ( $f_{\nu_i}/f_{\nu_j}$ , assuming  $f_{\nu} \propto \nu^{-1}$ ) can be used to correct each band, using Table 2. This procedure converts the actual bandwidths to

$$\Delta\nu_i = \int_0^{\infty} d\nu R_{i,\nu} (f_{\nu}/f_{\nu_i}), \quad (3.4)$$

with  $f_{\nu}$  the true source spectrum, or map pixel spectrum normalized to its value on the nominal frequency of the band.

There are two ways in which theoretical infrared spectra can be related to IRAS observations: (i) A theoretical model spectrum can be used to predict the IRAS in-band intensities by numerically integrating the model's calculated specific intensities convolved with the relative system response. In this case no colour correction is needed; (ii) Obtaining colour corrected (*i.e.* true) specific intensities at the nominal band centres and relating these to the predicted model's specific intensities. The second method is more direct. A general set of colour correction tables can be found in Leene (1987).

Table 1. IRAS wavelength band characteristics. <sup>a)</sup>

Quantity		Unit	12 $\mu\text{m}$	25 $\mu\text{m}$	60 $\mu\text{m}$	100 $\mu\text{m}$
Nominal band centre:	$\nu_i$	$10^{12}$ Hz	25	12	5	3
	$\tilde{\nu}_i$	$\text{cm}^{-1}$	833	400	167	100
$\nu f_\nu/\Delta\nu f_\nu$			1.85	2.32	1.94	3.00
Bandwidth:	$\Delta\lambda$	$\mu\text{m}$	7.0	11.15	32.5	31.5
	$\Delta\nu$	$10^{12}$ Hz	13.48	5.16	2.58	1.00
Zero-magnitudes:	$f_\nu$	Jy	28.3	6.73	1.19	0.43
	$F_\lambda$	$10^{-20}$ Watt $\text{cm}^{-2}$ $\mu\text{m}^{-1}$	5890	323	9.91	1.29
Zero-magnitudes:	$f_\nu^E$	$10^{-15}$ Watt $\text{m}^{-2}$	4120	360	32.2	4.06
	$f_\nu^W$	$10^{-15}$ Watt $\text{m}^{-2}$	5130	448	40.0	4.86

Notes to Table 1:

a) The values for  $f_\nu^E$  for a 10000 K blackbody are derived from colour correction with values quoted in IRAS (1985a). The numbers quoted by Waters  $f_\nu^W$  use an interpolation over the infrared band.

Figure 1. Colour correction factors for the four IRAS bands, for power-law spectra ( $f_\nu \propto \nu^n$ , with  $-10 < n < +10$ ) and for modified blackbodies ( $\nu^{1.5} B_\nu(T_d)$ , with  $0 \text{ K} < T_d < 100 \text{ K}$ ). The correct flux densities are obtained from  $f_\nu^{\text{correct}} = f_\nu^{\text{quoted}}/K_\nu$ .

Table 2.A. Table for colour corrections of intrinsic power law spectra.

Intrinsic Spectral Power	Colour-correction factors				Band ratios before correction		
	K	K	K	K	12 $\mu$ m	25 $\mu$ m	60 $\mu$ m

There are various uncertainties, related to the subjects in this section. The first are calibration uncertainties; these are at least 10 %. The accuracy of the bandwidth and the colour correction are uncertain. A comparison of Waters *et al.* (1987) with IRAS (1985a) for  $10^4$  K stars, see blackbody in Table 1, gives indications for an uncertainty of 20 – 30 % in the zero-magnitude flux density, solely on the basis of interpolations over the bands. For dust emission this uncertainty is less than for the steep spectra of stars.

The calibration of SMC and LMC IRAS Additional Observations is discussed in Chapters II and III; a discussion of convolved data is given in Chapter V.

#### 4. Dust properties and radiative transfer theory

##### 4.1. Dust properties

In principle, dust grains are formed in the cool (1000 K) and dense ( $10^{19}$  particles  $\text{m}^{-3}$ ) outer layers of late type giant stars (Hasegawa, 1984; Dyson and Williams, 1980). The interstellar medium has a density which is too low to produce dust grains of  $10^{10}$  atoms (with radii  $a$  of  $0.1 \mu\text{m}$ ); dust grains are removed from the stellar envelope by stellar winds and they evolve and grow in the interstellar medium (Greenberg, 1984). They are disrupted by photo- or shock-dissociation (see Seab and Shull, 1984; Dwek, 1988; Heiles, 1988). Mass, size, shape and chemical composition differ for all grains and dust properties are therefore only average properties of an ensemble. Mathis *et al.* (1977) have derived a grain size distribution for normal grains, from the ultraviolet extinction curve of  $n(a) \propto a^{-3.5}$  with  $a_{\min} = 0.01 \mu\text{m}$  and  $a_{\max} = 0.25 \mu\text{m}$  (the MRN grain size distribution). Other models have been proposed by various people (*e.g.* Draine and Anderson, 1985), which increase the number of smaller grains relatively to the number of larger "normal" grains. These grains have radii as small as 0.3 nm and can be regarded as large molecules (Polycyclic Aromatic Hydrocarbons or PAHs; Puget *et al.*, 1985).

We give an estimate for the infrared spectrum of very small grains. From Draine and Anderson (1985) we find the infrared spectrum for modified MRN grain models. We derived the spectrum for grains with  $0.3 \text{ nm} < a < 3 \text{ nm}$ , in a Solar Neighbourhood radiation field from the difference between the curves labeled with  $a_{\min} = 3 \text{ \AA}$ , and  $a_{\min} = 30 \text{ \AA}$ . The relative spectral shape of the small grains is 1, 3, 4.5, 0 at 12, 25, 60 and  $100 \mu\text{m}$ .

Grains interact in three ways with radiation: by emission, absorption and scattering. For infrared wavelengths (IR) only the first two are important. What happens to a single grain with radius  $a$  when it is hit by a visual (V) or ultraviolet (UV) photon with energy  $h\nu_{ph}$  is described as follows. By absorbing the photon, the grain increases its energy and heats up from the initial temperature  $T_0$  to  $T_1$ , depending on the heat capacity per volume  $C_V(T)$ , via

$$h\nu_{ph} = \frac{4}{3}\pi a^3 \int_{T_0}^{T_1} dT C_V(T). \quad (4.1)$$

Due to this increase in temperature, the emission is increased from  $B_\nu(T_0)$  to  $B_\nu(T_1)$ . If the photon energy is very high compared to the heat capacity the increase in temperature may be so high that the grain sublimates. Especially small grains ( $a < 1 \text{ nm}$ ), that are

responsible for the mid-infrared excess emission, have strong temperature fluctuations due to single photon encounters (see Draine and Anderson, 1985; Puget *et al.* 1985). The larger grains are not warmed up much by single photon encounters and are assumed to be in equilibrium:  $W_{UV, in} = W_{IR, out}$ . The density of the radiation field influences the minimum grain radius  $a_{min}$ . A discussion of these very small grains in the Magellanic Clouds is given in Chapter VI.

For wavelengths (UV) comparable to grain radii  $a$  the absorption cross-section  $\sigma_\nu^{abs}$  is nearly equal to the geometrical cross-section  $\sigma^{geom} \equiv \pi a^2$ , and by Babinet's principle the scattering cross-section  $\sigma_\nu^{scat}$  is also nearly equal to  $\sigma^{geom}$ ; thus  $\sigma_\nu^{tot} = \sigma_\nu^{abs} + \sigma_\nu^{scat} \approx 2 \sigma^{geom}$  ( $\lambda = c/\nu \approx a$ ). At  $\lambda = 0.2 \mu m$  a resonance occurs with  $\sigma_\nu^{tot} \approx 3 \sigma^{geom}$  (the 2200 Å bump). For  $\lambda \gg a$  (IR)  $\sigma_\nu^{scat} \rightarrow 0$  and  $\sigma_\nu^{tot} = \sigma_\nu^{abs}$ . The extinction is the total amount of radiation lost from a specific beam from a certain direction (absorption and scattering) minus that scattered back in the beam.

The absorption efficiency of the grains  $Q_\nu^{abs}$  is defined as the ratio of the effective absorption cross-section  $\sigma_\nu^{abs}$  of the grains at frequency  $\nu$  and the geometrical cross-section  $\sigma^{geom} \equiv \pi a^2$ , i.e.

$$Q_\nu^{abs} = \frac{\sigma_\nu}{\pi a^2}. \quad (4.2)$$

$Q_\nu^{ext} \equiv Q_\nu^{abs} + Q_\nu^{scat}$  with  $Q_\nu^{scat} = 0$  at infrared wavelengths and by Kirchhoff's law  $Q_\nu^{abs} = Q_\nu$ , the emission efficiency. Using these definitions, the optical depth  $\tau_\nu$  at this frequency over a spatial range  $R$  is written as

$$\tau_\nu = \int_R dr \alpha_\nu = \int_R dr n_d \pi a^2 Q_\nu = \int_R dr \rho_d \kappa_\nu \quad (4.3)$$

and the relation between the mass absorption coefficient (opacity)  $\kappa_\nu$  and the absorption efficiency coefficient  $Q_\nu$  becomes

$$\kappa_\nu = \frac{n_d}{\rho_d} \pi a^2 Q_\nu = \frac{3}{4a\rho_d} Q_\nu. \quad (4.4)$$

The transmission  $t_\nu$  is written as  $t_\nu = e^{-\tau_\nu}$ ; this gives the amount of radiation that passes through a region. In these equations,  $\alpha_\nu = n_d \sigma_\nu = \rho_d \kappa_\nu$  is the absorption coefficient,  $n_d$  is the number density of the grains (depends on the object; for the interstellar medium:  $n_d \rho_d / n_{HI} \rho_{HI} \approx 0.005 - 0.01$ ),  $a$  the average grain radius (0.1  $\mu m$ ) and  $\rho_d$  the density of the grain material ( $\sim 3 \text{ g cm}^{-3}$ ) and  $Q_{100\mu m} = 1/644$  (Hildebrand, 1983).

Now we describe the mass absorption coefficient  $\kappa_\nu$  ( $\text{cm}^2/\text{g}$ ) that we have used. Table 3 gives a summary of emissivity exponents  $n$ , in  $j_\nu \propto \nu^{+n}$ , as derived for a range of objects. Another quantity that is used often to describe the mass absorption coefficient is  $\sigma_\nu^H$  (the absorption of dust per H-atom). The two are related as follows:

$$\sigma_\nu^H \equiv \frac{\tau_\nu}{N_H} = \frac{1}{X(H)} \frac{M_d}{M_g} M_H \kappa_\nu \quad \text{cm}^2/\text{H-atom}, \quad (4.5)$$

where  $M_d = n_d m_d$  is the dust mass density and  $M_g = (n_H + 2 n_{H_2}) m_H / X(H)$  is the gas density and  $X(H)$  the fractional mass abundance of hydrogen ( $X_\odot(H) \approx 0.7$ ) (see *e.g.* Mezger *et al.*, 1982).

From Table 3 we find that cool objects (integrated emission of galaxies) have  $n = 2$  and the warmer  $n = 1$  (Chini *et al.*, 1984a; 1984b). Of course fits for cold objects are primarily based on low frequency points and fits for warm objects on high frequency points. Draine and Lee (1984) showed possible variations of  $Q_{abs}/a$  with temperature. Because we want a temperature independent factor we have adopted a mass absorption coefficient

$$\kappa_\nu \text{ (cm}^2 \text{ g}^{-1}\text{)} = \kappa_{100 \mu\text{m}} (\lambda/100\mu\text{m})^{-n} = \kappa_{100\mu\text{m}} (\nu/3 \times 10^{12} \text{Hz})^{+n} \quad (4.6)$$

with  $n = 1.5 \pm 0.5$  for  $50 \mu\text{m} < \lambda < 150 \mu\text{m}$  and  $\kappa_{100\mu\text{m}} = 40 \text{ cm}^2/\text{g}$ , probably correct within a factor of two. Use of this exponent  $n$  gives the lowest error in the derived temperatures. The factor  $\kappa_{100\mu\text{m}}$  was derived for  $n = 1.5$  in the same way as described in Hildebrand (1983).

We compared values for dust temperature  $T_d$  and dust mass  $M_d$  from the absorption coefficient of Hildebrand (1983) with our mass absorption coefficient. Our temperatures and masses are both lower than Hildebrand's by 0.9. There are small variations with  $T_d$ , decreasing  $M_d$  for increasing  $T_d$  (see Sections 5 and 7).

Here we list some uncertainties that are involved in dust properties, size distribution and chemical composition. The 1983 Chicago assumptions and most other data given in Table 3 are based on galactic values (mainly bright HII regions). It is unknown if these values are also valid for all type of dust grains in all kinds of galaxies, like *e.g.* the Magellanic Clouds. It is known that there are differences in extinction curves between the Clouds and the Galaxy (Nandy, 1984), differences in chemical abundances (C, N, O), differences in molecular content (CO). The small 2200 Å bump in the Clouds is described to the absence of graphite in the Clouds, which corresponds to the lower C abundance; indicating that most grains in the Clouds are based on silicate cores. The steep UV rise of the extinction curve suggests a steeper grains size distribution for small radii in the Clouds. The recent discovery of the absence of the silicate feature in some Magellanic Cloud HII region, (Roche *et al.*, 1987) makes this last statement less secure.

#### 4.2. Radiative transfer

As described in Section 2 most of the infrared emission is starlight, re-emitted by dust grains. Infalling ultraviolet and visual light heat up dust particles and these particles radiate like blackbody emitters of equilibrium temperature  $T_d$  (K) via the Planck intensity function

$$B_\nu(T) = \frac{2h\nu^3}{c^2} \frac{1}{e^{h\nu/kT_d} - 1}. \quad (4.7)$$

The volume emission coefficient  $j_\nu$  is written as

$$j_\nu = n_d \pi a^2 Q_\nu B_\nu(T_d) = \rho_d \kappa_\nu B_\nu(T_d) = \alpha_\nu B_\nu(T_d) \quad (4.8)$$

Table 3. Literature emissivity exponents  $n$ .

Reference	Year	Wavelength range ( $\mu\text{m}$ )	$n$	Temperature of dust (K)	Comments (object, model, fit)
Greenberg	1978	$\rightarrow \infty$	2	--	Asymptotic limit of $Q_{\text{abs}}$ for $\lambda \rightarrow \infty$ ; applies to mm region of spectrum; must be used with caution towards shorter wavelengths (even at $300\mu\text{m}$ ).
Mezger et al.	1982	40 - 1000	1.0-2.3	--	Model MRN; comparison of computed and observed absorption cross-sections per H-atom. Monotonically decreasing power $n$ with increasing wavelength ( $n = 1$ at $60\mu\text{m}$ ).

## Note to Table 3:

Values of n or T in brackets are adopted.

Abbreviations used are:

KAO : NASA's G.P. Kuiper Airborne Observatory (0.91 m).

MLO : Mount Lemmon Observatory (1.5 m).

MKO : Mauna Kea Observatory (2.2 m).

IRTF: NASA's Infrared Telescope Facility.

CTIO: Cerro Tololo Inter-American Observatory (4.0 m).

which is added in the (differential) radiative transfer equation along the line-of-sight  $l$

$$dI_\nu = j_\nu dl - \alpha_\nu I_\nu dl. \quad (4.9)$$

The first term on the right hand side is responsible for emission and the second term for absorption of infrared radiation. The formal solution of the radiative transfer equation between  $\tau_0$  and  $\tau_\nu$  gives for the intensity (radiance)

$$I_\nu(\tau_\nu) = I_\nu(\tau_0)e^{-\tau_\nu} + \int_{\tau_0}^{\tau_\nu} dt'_\nu S_\nu(t'_\nu) e^{-(\tau_\nu - t'_\nu)} \quad (4.10)$$

with  $S_\nu \equiv j_\nu/\alpha_\nu = B_\nu$  the source function (by Kirchhoff's law). If  $S_\nu$  is independent of  $\tau_\nu$  and a single temperature  $T$  is present, this equation reduces to  $I_\nu = S_\nu(1 - e^{-\tau_\nu})$ . In the opaque case ( $\tau_\nu \gg 1$ ) the emission is optically thick:  $I_\nu \approx S_\nu$ ; in the transparent case ( $\tau_\nu \ll 1$ ) the emission is optically thin:  $I_\nu \approx \tau_\nu S_\nu$ .

If the infrared background of the source is set to zero, the boundary condition  $I_\nu(\tau_0) \equiv 0$  holds. Far-infrared radiation is optically thin (typically  $\tau_{100\mu m} \approx 0.01$ , see Fazio, 1978; Hildebrand *et al.*, 1977), hence we expand the exponential function to zero order

$$I_\nu(\tau_\nu) \approx \int_0^{\tau_\nu} dt'_\nu S_\nu(t'_\nu) = \int_0^L dl \rho_d \kappa_\nu B_\nu(T_l). \quad (4.11)$$

The flux density of radiation from an object at distance  $D$  is found from integrating  $j_\nu$  over the whole volume  $V$  of the source and over all possible solid angles  $\Omega$ . Assuming isotropic radiation from an homogeneous object the measured flux (or irradiance) density becomes

$$f_\nu = \frac{1}{4\pi D^2} \int_\Omega d\Omega \int_V dV \rho_d \kappa_\nu B_\nu(T_d) = \frac{M_d \kappa_\nu B_\nu(T_d)}{D^2}. \quad (4.12)$$

If the object subtends a solid angle element  $\Delta\Omega$  perpendicular to the line-of-sight  $l$ , the average intensity is reconstructed over this solid angle  $I_\nu = f_\nu/\Delta\Omega$ . The detectors of the IRAS satellite measure in fact the flux in the band. The bandwidth correction has been explained in Section 3 and intensities have been obtained by dividing the solid angle subtended by each detector  $\Delta\Omega_{det}$  on the sky (see IRAS, 1985a; Table IV.A.1 therein).

With  $\kappa_\nu$  from Section 4.1,  $I_\nu$  has the following form, which we call modified blackbodies:

$$I_\nu = \kappa_\nu B_\nu(T) = \kappa_0 c^{-n} \nu^{+n} B_\nu(T) \quad \text{with} \quad \kappa_\nu = \kappa_0 (c/\nu)^{-n}. \quad (4.13)$$

These functions have their maximum emission where  $x \equiv \frac{h\nu}{kT}$  obeys  $x = (3+n)(1 - e^{-x})$ . Numerical evaluation of this equation gives the relation between  $\lambda(T)$  and  $T(K)$  (see Table 4).

**Table 4.** Peak values and integration constants of modified blackbodies.

$n$	$\lambda$ (m)	$T$ (K)	$\sigma_n$ (kg s <sup>-1</sup> K <sup>-4</sup> )
0.0 <sup>a)</sup>	5099		$5.67 \times 10^{-8}$
0.5	4256		$8.93 \times 10^{-7}$
1.0	3670		$1.51 \times 10^{-5}$
1.5	3235		$2.72 \times 10^{-4}$
2.0	2898		$5.15 \times 10^{-3}$
2.5	2627		$1.02 \times 10^{-1}$
3.0	2404		$2.13 \times 10^{-0}$

Note to Table 4:

- a) For  $n = 0.0$  we get the well known equation  $\pi F = \sigma T^4$ ,  
with  $\sigma$  the Stefan-Boltzman constant.

Integration of the modified blackbody functions leads to

$$\int_0^{\infty} d\nu I_{\nu} = \kappa_0 (\sigma_n/\pi) T^{4+n}, \quad (4.14)$$

where the  $\sigma_n$  are modified Stefan-Boltzman constants (see Table 4). Note that for  $n = 0$  we get the Stefan-Boltzman constant. These functions are used in Chapters IV, V and VI.

## 5. Dust temperature from infrared observations

In radio astronomy brightness temperature is a well known term  $T_b$ . It defines the temperature of a blackbody that gives rise to the measured intensity at the observed wavelength in the Rayleigh-Jeans approximation, *i.e.*

$$I_{\nu} = 2 \lambda^{-2} k T_b. \quad (5.1)$$

In fact, for a single source this equation gives different temperatures at different radio wavelengths, as the emission process is synchrotron radiation or Brehmstrahlung. In the infrared wavelength regime, we want to determine real physical temperatures. We assume that only continuum emission is present.

As pointed out in Section 2 dust particles are heated to temperatures at which they radiate at infrared wavelengths. Not all dust particles have the same temperature, some are embedded in and heated by HII regions, others are in more quiescent galactic regions and heated by the more diluted interstellar radiation field (ISRF). Along each line-of-sight

$l$ , and in integrated flux densities of objects, we see the contribution of various temperature components with mass density  $\rho_l$  merged together,

$$I_\nu = \int_l dl \rho_l \kappa_\nu B_\nu(T_l) = \int_T dT \rho_T \kappa_\nu B_\nu(T). \quad (5.2)$$

These integrands, which are modified blackbody functions have their maxima at  $\lambda$  ( $\mu\text{m}$ )  $T(\text{K}) \approx 5100 \frac{3}{3+n}$ , for  $\kappa_\nu \propto \nu^{+n}$ . To obtain dust temperatures we assume that colour corrected specific intensities have been obtained (see Section 3) and that a single line-of-sight temperature  $T_d$  applies (hence  $\rho_T = P_d \delta(T - T_d)$ ; with  $P_d$  the total dust mass in the line-of-sight). Then Equation (5.2) reduces to

$$I_\nu = P_d \kappa_\nu B_\nu(T_d). \quad (5.3)$$

Colour-temperatures are defined by relating the ratio of two spectral points to a blackbody. Our modified blackbodies give us "modified colour temperatures" which are the physical temperature of dust for the assumed emissivity. Using two specific intensity values, with similar resolution, at different frequency points  $\nu_1$  and  $\nu_2$  (from the IRAS 12, 25, 60 and 100  $\mu\text{m}$  bands), and assuming the same amount of dust  $P_d$  emitting at  $\nu_1$  and  $\nu_2$ , the ratio  $I_{\nu_1}/I_{\nu_2}$  gives us a recursive relation for  $T_d$  from

$$\frac{I_{\nu_1}}{I_{\nu_2}} = \frac{f_{\nu_1}/\Delta\Omega}{f_{\nu_2}/\Delta\Omega} = \frac{\kappa_{\nu_1}}{\kappa_{\nu_2}} \frac{B_{\nu_1}(T_d)}{B_{\nu_2}(T_d)}. \quad (5.4)$$

If  $\kappa_\nu$  depends on the dust temperature, itself its temperature dependence cancels in Equation (5.4). Note that similar resolutions must be used. The use of integrated flux densities works similar as the same factor  $\Delta\Omega$  occurs in numerator and denominator. For cool (20 – 50 K) galactic dust usually the 60 and 100  $\mu\text{m}$  points are used; and this formula reduces  $T_d$  to a direct equation

$$T_d = \frac{h(\nu_1 - \nu_2)}{k \ln\left(\left(\frac{\nu_1}{\nu_2}\right)^{3+n} \left(\frac{I_{\nu_2}}{I_{\nu_1}}\right) + C_T\right)}, \quad (5.5)$$

with a temperature dependent correction factor of

$$C_T = \left(1 - \left(\frac{\nu_1}{\nu_2}\right)^{3+n} \left(\frac{I_{\nu_2}}{I_{\nu_1}}\right)\right) e^{-h\nu_2/kT_d}. \quad (5.6)$$

$C_T$  gives the deviations of the true spectrum from the Wien regime of the blackbody spectrum. Leaving out  $C_T$ , i.e. assuming that we are in the Wien regime ( $h\nu_2 \gg kT_d$ ), while using the 60 and 100  $\mu\text{m}$  bands an error of less than 1 K for  $T_d < 45$  K is introduced, well below the (10 %) errors in the IRAS data; the value of  $C_T$  decreases monotonically from 0.0 ( $T_d = 0$  K) to -0.33 ( $T_d = 45$  K). At  $T_d = 80$  K ( $C_T = -0.46$ )

Equation (5.5) underestimates the "true" dust temperature by 10 %, independent of  $n$ ; the underestimation increases rapidly above this temperature. Iteration of Equations (5.5) and (5.6), may be used to find  $T_d$  with the requested accuracy. The relation between flux density ratios and  $T_d$  is given in Fig. 2 for  $n = 0 - 3$ . Fig. 2.1 gives the relation for the colour corrected flux densities, while Fig. 2.2 gives the relation for flux densities assuming  $f_\nu \propto \nu^{-1}$ . Table 5 gives the relation between  $T_d$  and  $I_{60\mu m}/I_{100\mu m}$  for  $n = 1.5$ , and also the relation between Fig. 2.1 and 2.2. An uncertainty in  $n$  of  $\Delta n = \pm 0.5$  results in a relative uncertainty in the temperature  $\Delta T/T = 10$  %. Define  $R \equiv \frac{I_{\nu_1}}{I_{\nu_2}}$ ; then we derive for the relative errors  $\frac{\Delta T}{T} = 0.4 \frac{\Delta R}{R}$ . For 10 % relative errors in  $I_\nu$ , the error in  $R$  is 14 %; and we get 4 % relative errors in  $T_d$ . For our temperature calculations in Chapters IV and V we have used tables of theoretical in-band intensity ratios.

The observed dust temperature gives us the possibility to separate dust components (2), (3) and (4) of Section 2. The energy of a single grain absorbed from the heating source per second is

$$W_a = \int_0^\infty d\nu \, 4\pi \, J_\nu \, \sigma_\nu^{abs}, \quad \text{with} \quad J_\nu \equiv \frac{1}{4\pi} \int d\Omega \, I_\nu; \quad (5.7)$$

with  $J_\nu$  the average intensity of the radiation field  $I_\nu$ . Comparing this value with the energy emitted per second by the radiation field (see Equation (4.14)),

$$W_e = \int_0^\infty d\nu \, 4\pi \, B_\nu(T_d) \, \sigma_\nu^{abs} \approx 4\pi \, \sigma_0^{abs} \, \sigma_n T^{4+n} \quad (5.8)$$

for various kinds of input radiation fields, gives equilibrium dust temperatures. Here  $\sigma_\nu^{abs} = \sigma_0^{abs} (c/\nu)^{-n}$ ; a numerical integration of  $\sigma_\nu^{abs}$ , as given by Mezger *et al.* (1982) may be used instead of the power-law. The (modified Stefan-Boltzman) constants  $\sigma_n$ , have been described in Section 4.2. Using the ISRF of Mathis *et al.* (1983) with

$$\int_{0.09\mu m}^{8\mu m} d\lambda \, 4\pi J_{\lambda,\odot} = 0.0217 \text{ erg cm}^{-2} \text{ s}^{-1} \quad (5.9)$$

gives an equilibrium temperature of 16 K, via

$$T^{4+n} \approx \frac{\langle \sigma_{vis} \rangle}{\langle \sigma_{FIR} \rangle} \int d\lambda \, 4\pi \, J_\lambda. \quad (5.10)$$

A comparison of the measured dust temperatures and the model radiation field temperatures yields estimates for the strength of the radiation field. Hence the equilibrium temperature serves as a selection criteria for the strength of the radiation field that heats the dust.

## Notes to Table 5:

- The in-band intensity ratios (column 2) for  $T$  have been calculated by convolving the true spectrum with the IRAS responsivity function (IRAS, 1985a).  
Use: Leiden AO-data and Co-added Survey data (see Schwering, 1986).
- Column 3 has been calculated by dividing column 2 by the bandwidths and assuming an  $f_{\nu} \propto \nu^{-1}$  intrinsic source spectrum.  
Use: Official IRAS products like PSC, SSS, Skyflux images (IRAS, 1985a).
- Column 4 gives the true ratio (after colour correction).
- Column 5 gives the ratio of column (3) and column (4); this results in the colour correction factors of Table 2.8.
- $f_{100 \mu\text{m}}$  for  $1 M_{\odot}$  of dust at 53 kpc (LMC) is calculated. At 63 kpc (SMC) the flux densities are 0.71 times as much.

Fig. 3 shows the relative contribution of two dust temperature components  $T_1$  and  $T_2$ , with different temperatures to the intensity in the line-of-sight. Fig. 3.1 uses a basic component  $T_1$  of 25 K, the temperature of dust heated by the general interstellar radiation field; Fig. 3.2 uses a basic component  $T_1$  of 50 K, typical HII regions dust temperatures. The component  $T_2$  varies from 0 to 100 K.

Fig. 4 shows the line-of-sight temperature that is reconstructed with Equations (5.5) and (5.6), if there are two temperature components in the line-of-sight. The basic components are set to 15 K (dust associated with H<sub>2</sub>), 25 K (dust associated with HI), and 50 and 75 K (HII region dust). The relative mass contribution is shown as labels to the curves: Although the calculated  $T_d$  (from  $I_{60\mu m}/I_{100\mu m}$ ) depends on the emissivity exponent  $n$  the calculated  $T_d$  from  $T_1$  and  $T_2$  is independent of  $n$ . Because the infrared intensity goes as a high power ( $4 + n$ ) of  $T_d$ , small fractions of hot dust give rise to high line-of-sight temperatures.

**Figure 4.** Effect of reconstructing dust temperatures in a line-of-sight with two temperature components. The first component  $M(T_1)$  is fixed at  $T_1$  (15, 25, 50 and 75 K), an amount  $M(T_2)$  of dust at  $T_2$  is added;  $T$  is the derived line-of-sight temperature.  $T_2$  varies from 0 to 100 K. The different curves are labeled according to the amount of dust at  $T_2$  relative to the amount of dust at  $T_1$ .

Temperature distributions are discussed in detail in Chapters IV (Galaxy) and V (Magellanic Clouds). In Chapter V we derive estimates for the radiation field in the Clouds. If the 60  $\mu\text{m}$  and 100  $\mu\text{m}$ , have partly different origins, *e.g.* part of the 60  $\mu\text{m}$  emission comes from very small grains, only that fraction of the emission in the bands must be taken that is coming from the same emission mechanism; otherwise  $T_d$  is too high. The same is true if an extra 100  $\mu\text{m}$  component is present; then  $T_d$  may be too low.

## 6. Far-infrared luminosity

A quantity that represents the total amount of infrared emission of objects is infrared luminosity  $L_{IR}$ . This quantity contains all the emitted infrared radiation and is an easy quantity to compare the infrared energy with *e.g.* visual energy. Galaxies emit a large part of their total infrared energy in the wavelength range covered by the IRAS 60 and 100  $\mu\text{m}$  bands.

The infrared luminosity is calculated from the infrared flux using the known distance  $D$  to objects:

$$L_{IR} = 4\pi D^2 F_{IR}. \quad (6.1)$$

In the first papers after the IRAS mission (see de Jong *et al.*, 1984) the following quantity was used to estimate for the far-infrared flux:

$$F80 \equiv f_{80} \nu_{80} \quad \text{where} \quad f_{80} \equiv (f_{60} + f_{100})/2 \quad (6.2)$$

with  $f_{60}$  and  $f_{100}$  the observed IRAS flux densities at 60 and 100  $\mu\text{m}$  respectively and  $\nu_{80}$  the 80  $\mu\text{m}$  frequency. Later another definition was given in "*Cataloged Galaxies and Quasars observed in the IRAS Survey*" (IRAS, 1985c) where the far-infrared parameter FIR is defined as:

$$FIR \equiv 1.26 (f_{60} \Delta\nu_{60} + f_{100} \Delta\nu_{100}) \approx \int_{42.5\mu\text{m}}^{122.5\mu\text{m}} d\nu f_\nu \quad (6.3)$$

with  $\Delta\nu_{60}$  and  $\Delta\nu_{100}$  the IRAS 60 and 100  $\mu\text{m}$  bandwidths (see Table 1). The factor 1.26 is used to fill the wavelength gap between these two IRAS bands.  $FIR$  is a good estimate for the flux that would have been measured within an ideal, square bandpass, 80  $\mu\text{m}$  wide, centered at 82.5  $\mu\text{m}$ . The emission of the thermal source is extremely well represented (within 1 %) for dust temperatures of 20 – 80 K and dust emissivity exponents ( $n = 0, 1, 2$ ): the ranges of interest for galaxies. Irrespective of the detailed shape of the emission.  $FIR$  neglects emission at both shorter and longer wavelengths and therefore does not estimate the total far infrared emission very well.

The quantity  $FIR$  is compared to  $F80$  as they resemble roughly the same thing. The relation is a function of the temperature of the dust (*i.e.*  $\alpha \equiv f_{60\mu\text{m}}/f_{100\mu\text{m}}$ ), and  $FIR/F80$  ranges from 0.67 for cool dust ( $\alpha = 0$ ) and is monotonically increasing up to 1.73 at the

other extreme ( $\alpha = \infty$ ).  $FIR$  equals  $F80$  for  $\alpha = 0.45$ , and for cool galactic dust with  $\alpha \approx 0.2$  (Buat and Deharveng, 1987) the ratio is 0.85.

The total far-infrared emission ( $1 - 500 \mu\text{m}$ )  $TIR$  is found from  $FIR$  using the factors of Table 6.A. Figure 5.1 displays these values for  $n = 0 - 3$ . These bolometric correction factors extrapolate  $FIR$  over the whole infrared wavelength range using  $I_{60\mu\text{m}}/I_{100\mu\text{m}}$  as a single temperature indication of the dust  $T_d$  and assuming the appropriate emissivity exponent  $n$ . The ratio  $TIR/FIR$  strongly depends on  $n$  and on  $T_d$ . The uncertainty in  $n$  ( $\pm 0.5$ ) gives a relative uncertainty in  $TIR/FIR$  of 20 %.

Fig. 5.1.  $TIR/FIR$ .Fig. 5.2.  $TIR/MIR$ .

**Figure 5.** Bolometric correction factors. For different emissivities, labeled  $n$  in the figure, correction factors are given at dust temperatures of 0 – 100 K, in order to integrate the observed far-infrared emission ( $FIR$ ) and 0 – 1000 K to integrate the mid-infrared emission ( $MIR$ ) over all wavelengths.

The 12 and 25  $\mu\text{m}$  emission as measured by IRAS are not fit very well with the 60/100  $\mu\text{m}$  dust temperature. A two component model is better (one representing the 60 and 100  $\mu\text{m}$  emission and the other the 12 and 25  $\mu\text{m}$  emission), each extrapolated over the infrared wavelength range separately and added afterwards. Analog to  $FIR$  we define  $MIR$  that gives the amount of mid-infrared radiation (between 8 and 30  $\mu\text{m}$ )

$$MIR \equiv 1.26 (f_{12}\Delta\nu_{12} + f_{25}\Delta\nu_{25}) \approx \int_{8\mu\text{m}}^{30\mu\text{m}} d\nu f_\nu. \quad (6.4)$$

The same factor of 1.26 is used, as this approximately fills the band gap. Extrapolating the 12 and 25  $\mu\text{m}$  points using a blackbody spectrum (with  $T$  depending on the ratio  $I_{12\mu\text{m}}/I_{25\mu\text{m}}$ ) gives us an estimate for the total flux in this component. Table 6.B and Figure 5.2 give these factors for values of  $n$  between  $-2$  and  $+3$  (note that the value  $n = 1.5$  for the emissivity exponent is not valid for  $\lambda < 50 \mu\text{m}$ ). When we do not take into account the emission of cold (15 K) dust in the very-far infrared ( $\lambda > 250 \mu\text{m}$ ), the total infrared emission is the sum of the extrapolated *FIR* and *MIR*:

$$F_{\text{IR}} = \left(\frac{T_{\text{IR}}}{F_{\text{IR}}}\right) F_{\text{IR}} + \left(\frac{T_{\text{IR}}}{M_{\text{IR}}}\right) M_{\text{IR}}. \quad (6.5)$$

The Clouds integrated infrared luminosities are subjects of Chapter V. Detailed maps of the infrared luminosities are shown in Chapter VII.

## 7. Optical depth, dust column density and dust masses

For the ideal object with a homogeneous composition we are now in a situation where we can find integrated dust properties. Let us assume here that our object indeed fulfills this criterium.

In nearly all astronomical cases the optical depth determined from the spectra at wavelengths longer than 100  $\mu\text{m}$  are found to be very much less than 1. Hence the observed flux densities sample with equal efficiency emission from all depths in the object. The optical depth for a homogeneous object is then found from

$$\tau_\nu = -\ln \left(1 - \frac{I_\nu}{B_\nu(T_d)}\right) \approx \frac{I_\nu}{B_\nu(T_d)} \quad \text{for } \tau_\nu \ll 1. \quad (7.1)$$

The characteristic that the emission is optically thin allows us to obtain dust masses from spatially integrated flux densities via (4.12)

$$M_d = \frac{f_\nu D^2}{\kappa_\nu B_\nu(T_d)}. \quad (7.2)$$

Here  $D$  is the distance to the object that emits the radiation. When using intensities instead of flux densities we cannot just invert Equation (5.3) because then we would get the mass of dust that radiates in a single line-of-sight. We assume isotropic radiation and we make use of the relation  $I_\nu = f_\nu/\Delta\Omega$ , where  $\Delta\Omega$  is the solid angle of an area of which the mass has to be calculated (*e.g.* dust mass per beam). The equation for dust mass becomes

$$M_d = \frac{I_\nu D^2 \Delta\Omega}{\kappa_\nu B_\nu(T_d)}. \quad (7.3)$$

Table 5 gives 100  $\mu\text{m}$  flux densities that would be observed for sources of  $1 M_\odot$  at the distance of the LMC (53 kpc). If  $\kappa_\nu$  depends on  $T_d$ , the exact relation  $\kappa_\nu(T_d)$  affects the

dust mass (see Draine and Lee, 1984; Dwek, 1988). The dust mass column density (when  $\Delta\Omega$  is the solid angle of a  $1 \text{ cm}^2$  column) is found from

$$\tilde{N}_d = \frac{M_d}{D^2 \Delta\Omega} = \frac{I_\nu}{\kappa_\nu B_\nu(T_d)}. \quad (7.4)$$

This column density, as the optical depth, measures the whole line-of-sight and is therefore independent of distance. The above can be transformed in a dust particle column density by dividing by the mass of an average grain  $m_d = 4/3 \pi a^3 \rho_d \approx 1.3 \times 10^{-17} \text{ kg}$  ( $7.6 \times 10^9$  a.m.u.):  $N_d = \tilde{N}_d/m_d$ . In Chapter IV we use  $N_d \equiv \tilde{N}_d/m_{HI}$ , with  $m_{HI}$  the mass of a hydrogen atom ( $1.67 \times 10^{-27} \text{ kg}$ ) to estimate the Galactic foreground dust column. Dust column densities in the Clouds are discussed in Chapter VI. In Chapter VII we discuss dust-to-gas ratios and luminosity-to-mass ratios for the Clouds.

The poor knowledge of  $\kappa_\nu$  at wavelengths below  $30 \mu\text{m}$  makes the estimation of dust masses in that component very uncertain. The dust mass for this component is very small because of the high dust temperatures. Most of the dust in galaxies emits in the  $60$  and  $100 \mu\text{m}$  range and hence the total dust mass is not influenced by mid-infrared emission.

## 8. Multiple dust components contributing to the infrared emission

A method for fitting an  $n$ -component model ( $n \leq 3$ ) to the four bands of IRAS data was started at Leiden Observatory by Braun (1985). A description of this method is given by Walterbos and Schwing (1987). Another model to predict the far-infrared emission, is given by Buat and Deharveng (1987). Rowan-Robinson (1987) describes various models. These models assume fixed temperature components.

From inspection of the Magellanic Cloud infrared maps we noticed varying temperatures over the whole face of the Clouds. Modelling of those maps, similar to modelling done by Walterbos and Schwing (1987) on M31, did not give a result of the same quality.

In Chapter VI we have used another method to decompose temperature components in each line-of-sight. First of all, we calculated line-of-sight dust temperatures, as explained in Section 5. This also gives the dust column densities via Section 7. In the case that temperature variations are excluded both  $T_d$  and  $M_d$  are correct (*e.g.* if the line-of-sight is short). These column densities are assumed to be lower limits as the temperature is biased towards high infrared intensities; hence we obtain  $M_l$ . We have maps of  $T_d$  and  $M_d$ , based on line-of-sight data. We calculate the lowest temperature  $T_{low}$  and the highest temperature  $T_{high}$  for the object. We divide this range in temperature steps  $\Delta T$ , and, starting at  $T_i = T_{low}$ , calculate for each  $T_i = T_{i-1} + \Delta T$  in the range, the area covered by dust of this temperature. We then assume that in all lines-of-sight with  $T_d > T_i$ , also dust is present of temperature  $T_i$ , and take its mass surface density equal to the average of the observed density in the region with  $T_d = T_i$ . We correct infrared intensities for this component to conserve the total infrared flux, and continue up to  $T_i = T_{high}$ . The mass in each component is the sum of all lines-of-sight in each component. The mass in each line-of-sight is the sum of all components in that line-of-sight. The total dust mass is the sum of all components. This is an upper limit, as some lines-of-sight are dominated by the warmer dust, while others are thin; hence we obtain  $M_u$ . The best estimate for the

dust mass is then set to  $(M_l + M_u)/2$ . The mass of the cold (15 K) dust component cannot be obtained from IRAS observations alone, but need additional observations at sub-mm wavelengths.

## 9. Summary

In this appendix we described the basic quantities that are of importance in interpreting far-infrared IRAS data. In relation to the data itself, some uncertainties are mentioned in Section 3 and we discussed the colour corrections, that have to be applied to the IRAS data, in detail. Colour correction tables and figures are included.

Dust characteristics are studied in Section 4. From a list of observed and theoretical spectra we have obtained an average emissivity in the far-infrared ( $\lambda > 40 \mu\text{m}$ ), using  $Q_\nu$  of Hildebrand (1983) for the absolute scaling:  $\kappa_\nu (\text{cm}^2 \text{g}^{-1}) = 40 (c/\nu)^{-1.5}$ . Through our work we have used this dust absorption coefficient to derive dust temperatures and dust masses. At shorter wavelengths ( $\lambda < 40 \mu\text{m}$ ) we derived temperatures using  $\kappa_\nu = \text{constant}$  (hence we obtained colour temperatures).

In Section 5 we have derived an equation to calculate dust temperatures, and we have discussed the relation of the temperature and the radiation field. A table with band ratios for different dust temperatures, based on different types of IRAS data, is given; figures are included. In Section 6 we obtained quantities to find the total infrared luminosity of objects. Tables and figures, giving the bolometric correction factors, are included. The dust mass calculation procedure is explained in Section 7 and Section 8 gives a new method to estimate dust masses in thick galaxies.

## Summary

This thesis presents the results of an extensive study of the infrared and dust properties of the Magellanic Clouds.

The space between stars is emptier than the best vacua produced in the laboratory. However, it still contains large amounts of gas and dust. The main form of gas is hydrogen. Dust (also called smoke) can be observed indirectly by its absorption of visual light of stars. This effect is more important at higher frequencies, resulting in the reddening of light. In most cases, infrared emission is not absorbed by dust.

The origin of infrared emission is dust. Dust grains consist of about  $10^{10}$  atoms and have an average radius of  $0.1 \mu\text{m}$ . Dust is formed in the outer layers of stars in their latest evolution phases, after which it is sent into interstellar space. Accumulations of dust can occur and molecular hydrogen can form on their surfaces. Dust grains are heated by the general interstellar radiation field or by closeby complexes of young stars. The temperature of the dust varies from  $-260^\circ\text{C}$  to  $-200^\circ\text{C}$ . This is warm enough to emit infrared emission with a maximum in the spectrum between 50 and  $200 \mu\text{m}$ .

Together with M31 and M33 the Magellanic Clouds are the only two galaxies that could be resolved in substantial detail with the Infrared Astronomical Satellite (IRAS). Because of their closeness, details of order 10 times smaller than in the nearest spiral galaxy M31 and 50 times smaller than in comparable dwarf irregular galaxies can be seen. General morphological aspects of the infrared emission, relations between infrared emission and other wavelength data and properties of dust in the Magellanic Clouds are discussed. The infrared Galactic foreground in the direction of the Clouds is also discussed.

Chapter II describes the observations of the SMC obtained with the IRAS satellite. Maps are presented at wavelengths of 12, 25, 60 and  $100 \mu\text{m}$ . From these maps a list of 219 discrete infrared sources is extracted. This source list is compared to known object lists (foreground stars, SMC stars,  $\text{H}\alpha$  nebulosities, clusters, supernova remnants, planetary nebula and dark clouds). There is a good correlation between HII regions and infrared emission from the SMC. In an Appendix a discussion of two fields at the SE and SW edges of the SMC is given. These areas contain 29 sources, which are also compared to other source lists.

Chapter III deals with IRAS infrared observations of the LMC. A similar presentation and discussion is given as for the SMC. A list of 1823 discrete sources is extracted, which is compared to similar source lists as in Chapter II. Seven fields at the North and West edges of the LMC are discussed in an Appendix. These fields contain another 68 sources, which are also compared to other source lists. As for the SMC, there is also a very good correlation of the infrared emission peaks with HII regions in the LMC.

Chapter IV contains a discussion of the Galactic infrared foreground emission. Until now most authors assume a constant Galactic foreground reddening towards the LMC of 0.07 magnitude. Foreground filaments disturb the image of this Cloud, and the IRAS data show significant variations in the foreground. The relation between the infrared foreground emission and the atomic hydrogen content is discussed and it is found to be non-linear. Infrared maps were corrected for temperature effects. These maps are compared to the atomic hydrogen emission. An estimate for the foreground infrared emission is derived, based on the average gas-to-dust ratio. The foreground towards the LMC varies from 0.07

to 0.17 magnitude, with an average of 0.10. The foreground towards 30 Doradus shows less extinction than towards other LMC regions. One of the implications is that studies of the LMC in the visual and ultraviolet wavelength regions should be corrected for a varying foreground. A more or less constant foreground of 0.08 magnitude towards the SMC is found.

Chapter V deals with the global properties of the Magellanic Clouds. Integrated infrared flux densities, infrared sizes, infrared luminosities and dust temperatures are derived. The infrared morphology is discussed, together with the temperature distribution. It turns out that the Greater 30 Doradus Region emits about 40 % of all infrared radiation. The density of the interstellar radiation field in the Clouds is derived. In some HII regions it is more than 10 times stronger than in the Galaxy, while the radiation fields at the edge of the Clouds are comparable to that in the Solar Neighbourhood. On average the fields are 7 times stronger than the Solar Neighbourhood field. A relation is found between infrared emission and the H $\alpha$  supergiant shells in the LMC. Comparisons of the infrared maps are presented with ultraviolet data, H $\alpha$  maps and with radio continuum observations. This shows the relation of the infrared emission with the radiation field in the Clouds. The spectral shape of the Clouds is similar to that of another irregular galaxy NGC 4449, but very different from that of M31. The SMC is 10 to 20 times weaker than the LMC in the infrared.

Chapter VI presents a discussion of the dust properties in the Magellanic Clouds. The mid-infrared (12 and 25  $\mu\text{m}$ ) emission is discussed in detail. This emission in the Clouds is less than that in the Local Group spiral galaxies. It is most likely that very small grains are responsible for this emission. Dust masses are derived for the combined warm ( $\sim 50$  K) and cool (25 K) dust components. The mass present in the cold (15 K) dust component is estimated to be between 1/3 and 1 times the mass of cool dust. Total dust masses of 550 000 solar masses for the LMC and 24 000 solar masses for the SMC are derived. Dust column density maps are presented for both Clouds. From a comparison of the infrared maps with atomic hydrogen maps, similar non-linear relations are found as for the Galactic foreground in Chapter IV.

Chapter VII contains a further discussion of the global properties of the Clouds, the relation of the Clouds with irregular galaxies and the relation of the Clouds with Local Group spiral galaxies. The infrared colours of the Clouds are similar to the colours of other irregular galaxies. There are some exceptions, NGC 6822 and NGC 1569 have much lower  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  ratios than the Clouds, but their  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  ratios are similar. The luminosity-to-mass ratio of the SMC is similar to that of other irregular galaxies. That ratio of the LMC is an order of magnitude higher, and is comparable to that of spiral galaxies such as IC 342, M101 and M33. Relative to the irregular galaxies, the gas-to-dust ratio in the LMC is low. Again NGC 1569 is an exceptional case. In the colour-colour diagrams, the Local Group spiral galaxies are clearly separated from the irregular galaxies, showing relatively cool dust emission in those galaxies. The LMC gas-to-dust ratio is probably not very different from that in M31 and M33. The gas-to-dust ratio in the Clouds is discussed. For the LMC a ratio 3 times higher than for the Milky Way is found; for the SMC the ratio is 50 times higher than for the Milky Way. The LMC value agrees well with that of other authors, based on photometric B and V measurements and Ly $\alpha$  absorption. The SMC value is, however, 3 to 6 times higher than those ratios. This

difference is explained by Galactic foreground difficulties in photometric observations: high foreground extinction values from Chapter IV suggest large variations on small scales for individual stars. A new fit is made to the  $E_{B-V}$  and  $N_{HI}$  data, showing agreement with the dust mass based on infrared data. These findings also agree with the integrated ratio  $L_{100\mu m}/M_{HI}$ , which is about 30 times lower for the SMC than for the Galaxy.

In an Appendix, a description of the far-infrared radiative transfer theory is given. It also contains tables and figures for colour corrections, temperature calculations and bolometric corrections.

## Resumen

En esta tesis se presentan los resultados de un extenso estudio de las propiedades del infrarrojo y del polvo de las Nubes de Magallanes.

El espacio existente entre las estrellas es más vacío que el mejor "vacuum" producido en el laboratorio. Pero, aún así, contiene grandes cantidades de gas y polvo. La principal forma de gas es el hidrógeno. El polvo puede ser observado indirectamente debido a su absorción de la luz visual de las estrellas. Este efecto es más importante a frecuencias más altas, resultando en un enrojecimiento de la luz. En la mayoría de los casos, la emisión infrarroja no es absorbida por el polvo.

El origen de la emisión infrarroja es el polvo. Las partículas de polvo consisten de, aproximadamente,  $10^{10}$  átomos y tienen un radio promedio de  $0.1 \mu\text{m}$ . El polvo se forma en las capas externas de las estrellas, en sus últimas fases de evolución, después de lo cual es enviado al espacio interestelar. Puede acumularse el polvo y formarse hidrógeno molecular en sus superficies. Las partículas de polvo son calentadas por el campo general de radiación interestelar o por complejos cercanos de estrellas jóvenes. La temperatura del polvo varía de  $-260^\circ\text{C}$  a  $-200^\circ\text{C}$ . Esta es lo suficientemente caliente para emitir radiación infrarroja con un máximo en el espectro entre 50 y  $200 \mu\text{m}$ .

Junto con la M31 y la M33, las Nubes de Magallanes son las únicas dos galaxias que podrían ser resueltas en gran detalle con el Satélite Astronómico Infrarrojo (IRAS). Debido a su proximidad pueden ser vistos detalles del orden de 10 veces más pequeños que en la galaxia espiral más próxima, la M31, y 50 veces más pequeños que en galaxias enanas irregulares comparables. Se discuten aspectos morfológicos generales de la emisión infrarroja, relaciones entre emisión infrarroja y otros datos de longitud de onda, y las propiedades del polvo en las Nubes de Magallanes. Se trata el frente Galáctico infrarrojo en dirección a las Nubes.

En el capítulo II se describen las observaciones de la Nube Menor de Magallanes, obtenidas con el satélite IRAS. Los mapas se presentan en longitudes de onda de 12, 25, 60 y  $100 \mu\text{m}$ . De estos mapas se extrajeron una lista de 219 fuentes discretas de infrarrojo. Esta lista de fuentes se compara a listas de objetos conocidos (estrellas de la Vía Láctea, estrellas de la Nube Menor, nebulosidades  $\text{H}\alpha$ , grupos de estrellas, remanentes de supernovas, nebulosa planetaria y nubes oscuras). Se muestra que hay una buena correlación entre las regiones HII y la emisión infrarroja desde la Nube Menor. En un apéndice de este capítulo se discuten dos zonas en los extremos SE y SO de la Nube Menor. Estas áreas contienen 29 fuentes que también se comparan a otras listas de fuentes.

El capítulo III versa sobre las observaciones en infrarrojo de la Nube Mayor de Magallanes, efectuadas con el IRAS. Se presenta una exposición y discusión similar sobre la Nube Menor. Se extrae una lista de 1823 fuentes discretas, la que se compara a las listas de fuentes similares al capítulo II. En un apéndice de este capítulo se discuten siete zonas en los extremos del Norte y Oeste de la Nube Mayor. Estas zonas contienen otras 68 fuentes, las cuales se comparan también a otras listas de fuentes. Se encuentra nuevamente una muy buena correlación de los puntos más altos de la emisión infrarroja y las regiones HII.

El capítulo IV contiene un análisis de la emisión del frente galáctico infrarrojo. Hasta ahora, la mayoría de los autores asume un constante enrojecimiento del frente galáctico

hacia la Nube Mayor de 0.07 magnitud. Filamentos del frente interfieren con la imagen de esta Nube y los datos obtenidos con el IRAS muestran fuertes variaciones en el frente. Se discute la relación entre la emisión infrarroja del frente y el contenido atómico del hidrógeno; se descubre que es no-lineal. Se corrigieron mapas infrarrojos para efectos de temperatura. Estos mapas se comparan con la emisión del hidrógeno atómico. Se deriva una estimación para el frente infrarrojo, basada en la proporción gas a polvo promedio. El frente hacia la Nube Mayor varía de 0.07 a 0.17 magnitud, con un promedio de 0.10. El frente hacia 30 Doradus muestra menos extinción que en otras regiones de la Nube Mayor. Una de las implicaciones al respecto es que estudios sobre la Nube Mayor, en las regiones de longitud de onda visual y ultravioleta, deberían ser corregidos por un frente variante. Hacia la Nube Menor se encuentra un frente de 0.08 magnitud.

El capítulo V trata de las propiedades globales de las Nubes de Magallanes. Se derivan densidades de flujo infrarrojo integrado, tamaños infrarrojos, luminosidades infrarrojas y temperaturas del polvo. Se discute la morfología infrarroja, junto con la distribución de la temperatura. Resulta que la región mayor del 30 Doradus, emite cerca del 40 % de toda la radiación infrarroja. Posteriormente se deriva la densidad de la zona de radiación interestelar en las Nubes. En algunas regiones HII es de 10 veces más potente que en la galaxia, mientras que las zonas de radiación en los extremos de las Nubes se comparan a aquellas en la proximidad solar. En promedio las zonas son 7 veces más potentes que la zona de proximidad solar. Se encuentra una relación entre la emisión infrarroja y los anillos super-gigantes  $H\alpha$  en la Nube Mayor. Se presentan comparaciones de los mapas infrarrojos con datos ultravioletas, con mapas  $H\alpha$  y con observaciones de radio continuo. Esto muestra la relación de la emisión infrarroja con la zona de radiación en las Nubes. La forma espectral de las Nubes es similar a la de otra galaxia irregular, la NGC 4449, pero muy diferente a la M31. En el infrarrojo, la Nube Menor es entre 10 y 20 veces más débil que la Nube Mayor.

En el capítulo VI se presenta un análisis de las propiedades del polvo en las Nubes de Magallanes. La emisión infrarroja-media (12 y 25  $\mu\text{m}$ ) se discute en detalle. En las Nubes esta emisión es menor que aquella en las galaxias espirales del Grupo Local. Lo más probable es que partículas muy pequeñas sean las responsables de esta emisión. Las masas de polvo se derivan para las componentes combinadas del polvo caliente (de  $-250^\circ\text{C}$  a  $-225^\circ\text{C}$ ) y frío. La masa presente en la componente del polvo frío ( $-260^\circ\text{C}$ ) se estima entre 1/3 y 1 veces la masa del polvo frío. Se derivan masas totales de polvo de 550 000 masas solares para la Nube Mayor y 24 000 masas solares para la Nube Menor. Se presentan, para ambas Nubes, mapas de densidad de columna del polvo. Al comparar los mapas infrarrojos con mapas de hidrógeno atómico, se encuentran relaciones no-lineales similares para el frente galáctico (ver capítulo IV).

El capítulo VII contiene un análisis más detenido de las propiedades globales de las Nubes, la relación de las Nubes con galaxias irregulares y la relación de las Nubes con las galaxias espirales del Grupo Local. Los colores infrarrojos de las Nubes son similares a los colores de otras galaxias irregulares. Hay algunas excepciones: la NGC 6822 y la NGC 1569 tienen proporciones de  $f_{12\mu\text{m}}/f_{25\mu\text{m}}$  mucho más bajas que las Nubes, pero sus proporciones de  $f_{60\mu\text{m}}/f_{100\mu\text{m}}$  son similares. La proporción luminosidad a masa de la Nube Menor es similar a la misma proporción para otras galaxias irregulares. La proporción de la Nube Mayor es un factor de 10 más alto y está entre varias galaxias espirales como la IC342,

M101 y la M33. En relación a las galaxias irregulares, la proporción gas a polvo en la Nube Mayor es baja. Nuevamente, la NGC 1569 es un caso excepcional. En los diagramas color contra color, las galaxias espirales del Grupo Local están claramente separadas de las galaxias irregulares, mostrando una emisión de polvo relativamente frío en estas galaxias. La proporción gas a polvo de la Nube Mayor está probablemente no muy lejos de aquella en la M31 y M33. Mas aún, se discute la proporción gas a polvo en las Nubes. Para la Nube Mayor se encuentra una proporción de 3 veces más que el de la Vía Láctea; para la Nube Menor la proporción es 50 veces mayor que la de la Vía Láctea. El valor de la Nube Mayor concuerda bien con aquel de otros autores, basado en medidas fotométricas B y V y absorción  $\text{Ly}\alpha$ . El valor de la Nube Menor es, sin embargo, de 3 a 6 veces más alto que aquellas proporciones. Esta diferencia se explica por las dificultades en las observaciones fotométricas a consecuencia del frente galáctico: altos valores de extinción del frente en el capítulo IV sugieren grandes variaciones en pequeñas escalas para estrellas individuales. Se ha hecho un nuevo ajuste de los datos  $E_{B-V}$  y  $N_{HI}$ , mostrando concordancia con la masa del polvo basada en datos infrarrojos. Estos descubrimientos también concuerdan con la proporción integrada de  $L_{100\mu m}/M_{HI}$ , la cual es alrededor de 30 veces menor para la Nube Menor que para la Galaxia.

En un apéndice se presenta una descripción de la teoría de transferencia de radiación infrarroja-lejana. También contiene tablas y figuras para la corrección de colores, cálculos de temperaturas y correcciones bolométricas.

## Samenvatting

In dit proefschrift worden de resultaten van een uitgebreid onderzoek van de infrarood- en stofeigenschappen van de Magelhaense Wolken, ook wel Kaapse Wolken, besproken.

De ruimte tussen de sterren is leger dan het beste Aardse vacuum, maar bevat toch grote hoeveelheden gas en stof. Het gas bestaat voornamelijk uit waterstof. Het stof, ook wel rook genoemd, kunnen we indirect waarnemen omdat dit het licht van sterren verzwakt. Dit effect speelt een grotere rol voor het ultraviolette en blauwe licht dan voor het rode en infrarode licht, waardoor het licht verkleurt (het wordt roder: verroding). Meestal wordt het infrarode licht niet verzwakt en meet de astronoom dus alle infrarode straling die door een bron wordt uitgezonden.

De oorzaak van deze infrarode straling is ditzelfde stof. Stofdeeltjes bestaan uit circa 10 miljard atomen en hebben een gemiddelde straal van een tienduizendste millimeter. Stof wordt gevormd in de laatste evolutie-fasen van sterren. Daarna wordt het in het interstellair medium verspreid, waar het zich kan ophopen en kan bijdragen aan de productie van waterstof-moleculen. In het interstellair medium wordt het stof opgewarmd door het gezamenlijke stralingsveld van alle sterren. Als het zich in een complex van jonge sterren bevindt zal het door deze sterren tot hogere temperaturen worden verhit. De temperatuur die zij hierbij krijgen varieert van  $-260^{\circ}\text{C}$  tot  $-200^{\circ}\text{C}$ . Dit is zo "warm" dat de stofdeeltjes infrarode straling gaan uitzenden met een maximale sterkte op golflengten tussen 50 en 200 micrometer (een twintigste tot een vijfde millimeter).

Samen met de Andromedanevel M31 en de Driehoeknevel M33, zijn de Magelhaense Wolken de enige melkwegstelsels die voldoende dichtbij staan om goed in detail te kunnen worden bestudeerd met de gegevens van de Infrarood Astronomische Satelliet (IRAS). Door hun nabijheid zijn tien maal kleinere details te zien dan in M31 en vijftig maal kleinere details dan in vergelijkbare onregelmatige sterrenstelsels. Er wordt een bespreking gegeven van de algemene morfologische aspecten van de infrarode emissie, de relaties tussen infrarode emissie en emissie bij andere golflengten, alsmede de eigenschappen van stof.

In hoofdstuk II worden IRAS waarnemingen van de Kleine Magelhaense Wolk gerepresenteerd in de vorm van volledige-resolutie kaarten bij golflengten van 12, 25, 60 en  $100\text{ }\mu\text{m}$ . Uit deze kaarten is een bronnenlijst met 219 discrete objecten samengesteld. Deze lijst is vergeleken met lijsten van andere objecten (voorgroond sterren, sterren in de Wolk,  $\text{H}\alpha$  emissielevels, clusters van sterren, supernova resten, planetaire nevels en donkere wolken). Er blijkt een goede correlatie te bestaan tussen de gebieden van geïoniseerde waterstof en gebieden van infrarode emissie in de Kleine Wolk. In een appendix worden twee velden aan de zuid-oost en zuid-west rand van de Kleine Wolk behandeld. Deze velden bevatten 29 infrarood-bronnen die eveneens zijn vergeleken met andere bronnenlijsten.

Hoofdstuk III behandelt de IRAS waarnemingen van de Grote Magelhaense Wolk in een vergelijkbare presentatie als voor de Kleine Wolk. In totaal bevinden zich 1823 bronnen in de hiermee verkregen bronnenlijst. Deze lijst is vergeleken met identieke lijsten als voor de Kleine Wolk in hoofdstuk II. Zeven velden aan de noordelijke en westelijke rand van de Wolk zijn in een appendix behandeld. Deze velden bevatten nog eens 68 bronnen. Ook voor de Grote Wolk blijkt er een goede overeenkomst te bestaan tussen infrarode emissie en gebieden van geïoniseerde waterstof.

In hoofdstuk IV wordt de infrarode straling van de Galactische voorgrond behandeld. Tot nu toe werd er altijd aangenomen dat de voorgrond in de richting van de Grote Magelhaense Wolk een egale verroding veroorzaakt van 0.07 magnitude. In deze richting bevinden zich verschillende voorgrond filamenten, en IRAS kaarten laten significante variaties in stofdichtheden zien. De relatie tussen de infrarode straling en de emissie van atomaire waterstof blijkt niet lineair te zijn. De infrarood-kaarten zijn gecorrigeerd voor de stoftemperatuur en vergeleken met waterstof. Hieruit wordt de gemiddelde voorgrond gas-stof verhouding bepaald. In de richting van de Grote Wolk varieert de verroding van 0.07 tot 0.17 magnitude, met een gemiddelde van 0.10. De voorgrond van de 30 Doradus-nevel vertoont minder verroding dan die van andere gebieden in de Grote Wolk. Een van de gevolgen is dat studies aan de Grote Wolk bij visuele of ultraviolette golflengten voor deze variërende voorgrond moeten worden gecorrigeerd. In de richting van de Kleine Wolk worden geen variaties gevonden en er wordt een verroding vastgesteld van 0.08 magnitude.

Hoofdstuk V behandelt de globale eigenschappen van de Magelhaense Wolken: geïntegreerde infrarood-helderheden, afmetingen van deze melkwegstelsels in het infrarood, lichtsterkten in het infrarood en stoftemperaturen zijn bepaald. Dit hoofdstuk bevat een uitgebreide behandeling van de infrarood-morfologie en de temperatuurverdeling. Het 30 Doradus gebied produceert 40 % van alle emissie in het infrarood. Het interstellair stralingsveld in de Wolken is berekend en blijkt aan de randen overeen te komen met het Galactische stralingsveld in de Zonsomgeving. In HII gebieden is het ruim 10 maal zo sterk en gemiddeld is het 7 maal zo sterk in beide Wolken. Er is een relatie gevonden tussen infrarode emissie en  $H\alpha$ -schillen in de Grote Wolk. Vergelijkingen van de infrarood-kaarten met ultraviolette gegevens,  $H\alpha$ -kaarten en radiocontinuum-waarnemingen zijn gedaan. Deze laten zien dat de infrarood-emissie is gerelateerd aan zware jonge sterren. De vorm van het infrarode spectrum is voor beide Wolken hetzelfde; het spectrum lijkt op dat van het grote onregelmatige stelsel NGC 4449. Het laat warmer stof zien dan het spectrum van M31. Bij infrarode golflengten is de Kleine Magelhaense Wolk 10 tot 20 maal zwakker dan de Grote Wolk.

In hoofdstuk VI wordt een discussie van de eigenschappen van het stof in de Magelhaense Wolken gegeven. Er is minder 12 en 25  $\mu\text{m}$  emissie in de Wolken dan in de spiraalnevels van de Lokale Groep. Zeer waarschijnlijk zijn zeer kleine stofdeeltjes verantwoordelijk voor deze emissie. Totale stofmassa's voor het warme ( $-225^\circ\text{C}$ ), koele ( $-250^\circ\text{C}$ ) en koude ( $-260^\circ\text{C}$ ) stof zijn afgeleid. De totale stofmassa's zijn 550 000 zonsmassa's voor de Grote en 24 000 zonsmassa's voor de Kleine Magelhaense Wolk. Kaarten met stof-kolomdichtheden zijn gepresenteerd en vergeleken met atomair waterstof: er is een goede correlatie. Een vergelijkbare niet-lineaire relatie tussen infrarode emissie en atomaire waterstof-emissie is gevonden als voor de Galactische voorgrond (zoals bediscussieerd in hoofdstuk IV).

Hoofdstuk VII bevat een discussie van de globale eigenschappen van de Magelhaense Wolken, de relatie van de Wolken met andere onregelmatige melkwegstelsels en de relatie van de Wolken met Locale Groep-stelsels. De infrarode kleuren van de Wolken komen goed overeen met die van de andere onregelmatige stelsels. Uitzonderingen daarop zijn NGC 6822 en NGC 1569, die een veel lagere verhouding van de straling bij 12 en 25  $\mu\text{m}$  hebben dan de Wolken; de 60 en 100  $\mu\text{m}$  stralingsverhouding is niet opmerkelijk verschillend. De lichtkracht-massa verhouding van de Kleine Wolk stemt overeen met

die van de andere onregelmatige stelsels; die van de Grote Wolk is een factor 10 hoger en valt tussen spiraalnevels als IC 342, M101 en M33. T.o.v de onregelmatige stelsels is de gas-stof verhouding in de Grote Wolk zeer laag. De kleuren van de Lokale Groep-spiraalstelsels zijn duidelijk verschillend van die van de onregelmatige stelsels. Dit laat zien dat zij koeler stof bevatten. De gas-stof verhouding in the Grote Wolk is bijna gelijk aan die in M33. De gas-stof verhouding in de Grote Wolk is bepaald op 3 maal, en die in de Kleine Wolk op 50 maal die in de melkweg. Deze waarde voor de Grote Wolk is ook door andere auteurs gevonden d.m.v. visuele en ultraviolette  $\text{Ly}\alpha$  metingen. De waarde voor de Kleine Wolk is 3 tot 6 maal hoger dan gevonden met laatstgenoemde methode. De hogere voorgrond-verroding, die in hoofdstuk IV gevonden is, voorspelt voor individuele sterren op kleine schaal sterke voorgrond stof variaties. Een nieuwe vergelijking is gemaakt van de visuele en ultraviolette gegevens die laat zien dat deze methode ook een hogere gas-stof verhouding kan geven. De gevonden verhouding is in overeenstemming met de lichtkracht-massa verhoudingen gevonden m.b.v geïntegreerde waarden.

In een appendix wordt een beschrijving gegeven van het stralingstransport. Ook bevat de appendix tabellen en figuren voor kleurcorrecties, temperatuur bepalingen en bolometrische correcties van IRAS gegevens.

## Curriculum Vitae

In juni 1978 behaalde ik het diploma Atheneum-B aan het Veurs College te Leidschendam. In september van dat jaar begon ik met de studie sterrenkunde aan de Rijksuniversiteit te Leiden. De eerste fase werd in april 1981 afgerond met het kandidaatsexamen A1 met hoofdvakken sterrenkunde en natuurkunde en bijvak wiskunde. Drie jaar later slaagde ik voor het doctoraal examen sterrenkunde met bijvak theoretische natuurkunde.

Tijdens de doctoraal fase volgde ik colleges van de hoogleraren Swarup, van de Hulst, van Schooneveld, Habing, Capel en Terwiel en van dr. van Leer. Gedurende een onderzoekje naar stationaire oplossingen van Burger's vergelijking d.m.v. impliciete tijdsafhankelijke differentieschemas, leerde dr. van Leer mij numeriek simuleren. Onder leiding van prof. W.B. Burton verrichte ik onderzoek aan de rotatiecurve van de melkweg m.b.v. 21-cm neutrale waterstof metingen van de Greenbank telescoop. Ik verhuisde voorgoed buiten de melkweg. Ik verwerkte en analyseerde, o.l.v. prof. W.W. Shane en dr. E. Brinks, 50-cm radiocontinuum metingen gemaakt met de Westerbork Synthese Radio Telescoop van het nabije melkwegstelsel, de Andromedanevel.

Het extragalactische werk werd voortgezet met het onderwerp van mijn proefschrift, de Magelhaense Wolken. Metingen gemaakt met de Infrarood Astronomische Satelliet zijn verwerkt, en de aanwezige informatie over de stofeigenschappen in deze naburige stelsels geanalyseerd. Het promotieonderzoek werd uitgevoerd tussen juni 1983 en augustus 1988, als wetenschappelijk assistent aan de Leidse universiteit. Voor mijn werk bezocht ik het IRAS grondcontrolestation in Chilton (U.K.), het Jet Propulsion Laboratory te Pasadena (U.S.A.) en de Europese Zuidelijke Sterrenwacht (ESO te Chile). Daarnaast bezocht ik IRAS software development workshops in Abingdon (U.K.), IPAC Pasadena (U.S.A.) en Groningen. Ik bezocht conferenties in zes plaatsen met een bijna evengroot aantal bijdragen: Nijmegen (1982), Groningen (1983), Toulouse (1984), Marseille (1985), Noordwijk (1985) en Les Arcs (1987).

Vanaf 1 december 1987 ben ik in dienst van het Fysisch en Electronisch Laboratorium van T.N.O. te 's-Gravenhage, waar ik aardse wolken bestudeer.

## Nawoord

Velen hebben aan de totstandkoming van dit proefschrift bijgedragen. Aan de wetenschappelijke kant hebben interacties met stafleden, promovendi en studenten een positieve invloed op het resultaat gehad. De sfeer op de Leidse Sterrewacht komen die interacties zeer ten goede.

Conferentie bezoeken zijn mogelijk gemaakt door financiële steun van het Leids Kerkhoven-Bosscha Fonds. Een bezoek aan het Jet Propulsion Laboratory te Pasadena werd gefinancierd door de Stichting Ruimte Onderzoek Nederland. Samen met Arnaud Leene verbleef ik in de nederlandse IRAS residentie in La Cañada Flintridge, een suburb van L.A. Y en uno de mis viajes para observar el cielo austral encontré una estrella muy especial.

Zonder de IRAS satelliet zou dit werk niet mogelijk zijn geweest. De figuren zijn bekwaam afgedrukt door W. Brokaar, L. Zuyderduin en J. Ober. Er is gebruik gemaakt van verschillende tekstverwerkers, hierbij was de hulp en het advies van velen onmisbaar. Verscheidene programmeurs hielpen bij software problemen, schijfruimte gebrek en datachecks: K. Lugtenborg, K. Weerstra, T. Hoekema, D. Hogeweg, P. Alphenaar en A. Vos. Hedy heeft zich vakkundig bezig gehouden met veel zaken. De mooiste herinneringen heb ik aan haar bijdrage in vele persoonlijke gesprekken.

Mijn ouders hebben mij de vrijheid gegeven om mijn eigen weg te volgen. Mimo siempre prepara rica comida. En los últimos tres años, Yoya ha enriquecido mi vida.
